Opinions as to consumption have varied considerably during the past forty years. Dr. William Budd was probably the first to recognize, about the year 1867, that the disease was infectious with a long period of incubation. Koch's discovery of the tubercle bacillus, while confirming Budd's views with regard to its infectivity, also opened up an era of much apprehension concerning the degree and source of this infectivity. Fears of extensive infectivity led to the establishment of sanatoria in all parts of the civilized world, in which sufferers were educated with respect to the precautions to be taken against disseminating the malady and were treated by open-air methods. At the same time tuberculosis was represented as a kind of plague, which unless it were checked would be the means of decimating any community in which it might have gained a foothold. Bulstrode now states that in his opinion, based upon his experiences of the past few years, that the menace of tuberculosis has been greatly exaggerated, and that instead of increasing it is steadily decreasing. In England and Wales during 1838 consumption killed 59,025 persons, a death rate equal to 39.9 for each 10,000 individuals living. In 1906, 39,746 died from the affection, a mortality equal to 11.5 for each 10,000 persons living. It has been computed that if the rate of decrease for the past thirty years were to be continued for thirty more, the disease would be extinct at the end of the period.

Another highly important point brought out by Dr. Bulstrode, or rather it should be said gathered by him as a result of his inquiries, is that the liability to direct infection through the air passages has been greatly overestimated, and many pathologists are of the opinion that the infection more often reaches the lungs through the alimentary canal and by the agency of disease germs swallowed in the mik or flesh of bovine animals. The conclusions which are in line with the conclusions come to by several other authorities are that tuberculosis milk and meat, more especially milk, may be the principal sources of danger to mankind. If this be so, a fresh sanitary problem is presented, the solution of which must be effected in order to cope successfully with the disease.

Sanatoria in England and Wales, according to Dr. Bulstrode, have not produced any perceptible effect upon the rate of decline of the consumption death rate. At best sanatorium treatment can form only part of the means whereby the ravages of tuberculosis generally may be stayed. At any rate, this report is yet another refutation, if such were needed, of Koch's dictum that the bovine tubercle bacillus was comparatively harmless to man. The results of almost all recent investigations go to show that milk and meat supplies require far more careful supervision than has been given to them up to the present time.

The MEDICAL RECORD has always taken the view that in the fight against tuberculosis the milk supply as a possible prominent factor in its dissemination should be stringently safeguarded. The milk supply of New York State and of America as a whole is better supervised than that of England, but there is no doubt that in both countries there is abundant room for further far-reaching reforms in this direction. It cannot be denied that sanatoria play an important part in checking the inroads of consumption, particularly in the early stages of the malady; but, on the other hand, a pure milk supply is at least of equal importance.

CARCINOMA OF THE PENIS.

SINCE carcinoma of the penis constitutes only from one to three per cent. of all carcinomata met with in men, statistics regarding it are not abundant, hence any report of a large number of cases giving the treatment and end results obtained is of value. In the December number of the *Annals of Surgery*, J. D. Barney reports one hundred unselected cases which he had examined and followed to the end. He found that this affection occurred most frequently in the fifth, sixth and seventh decades of life, and that man's civil state, occupation, contact with a carcinomatous cervix, and heredity played but little part in the etiology. It is worthy of note that the Hebrew race did not figure in the list of nations, and that out of forty-two cases, in which a note was made of the presence or absence of phimosis, the latter was present in thirty-six. He found the cauliflower type of growth to have been more frequent than the ulcerative with indurated edges, though the former was also usually ulcerated; there being a sanguino-purulent discharge in all. In sixty-nine per cent. of the cases the starting point was in the glands, while the remainder had their origin in the mucous membrane of the prepuce. Outside of a discharge and enlarged inguinal glands, the symptoms were usually late, consisting of disturbances during urination and of pain, although the latter was never particularly severe. The inguinal glands were pathologically enlarged in seventy-five per cent. of the cases, usually only on one side, but in only sixty per cent. were they cancerous; the others showed simply hyperplasia from septic absorption. Internal metastases in the pelvic organs and glands

were at times present without any enlargement of the inguinals; in fifteen per cent. of the cases there were deposits in the abdominal and thoracic organs. Seventy-four of Barney's patients had not been previously operated upon, twenty-six had been. As regards duration, from the first symptom to the final operation one to three years had elapsed, though it was over five years in eleven cases; this is quite natural when we consider that the disease entirely lacks severe initial symptoms and that one is not likely to detect any growth of small size under a congenitally tight prepuce. Of the recurrent cases six per cent. recurred between three and four years, and twelve per cent. five years after operation. The operations were usually only palliative, such as circumcision and excision; amputation alone was performed seven times. No recurrence was observed after amputation with excision of the inguinal glands.

In the twenty-six recurrent cases in which operation (amputation alone, sixteen cases; amputation with dissection of groins, four cases; palliative, six cases) was performed there were eleven definite cures, the average length of life being twenty-four years after operation; five of the men died from various causes, and ten from cancer, on an average of four years after the final operation.

Of the seventy-four primary cases, twenty-seven resulted in cure, *i. e.* life was prolonged for five years or more after operation and was terminated by other causes than cancer. The operations performed upon these twenty-seven cured cases were as follows: Amputation, twenty cases; amputation with dissection of groin, five cases; palliative, two cases. Twenty-two patients died of cancer, the average length of life after operation having been two years; the operations performed upon these were: Amputation, thirteen cases; amputation with dissection of groin, five cases; palliative, four cases. Fifteen of the seventy-four patients died of other causes and ten could not be followed; the operations performed upon those in these two groups were: Amputation, thirteen cases; amputation with dissection of groins, six cases; palliative, six cases.

It is important to recall the fact already mentioned that there was not a single Hebrew among the one hundred patients, and that phimosis existed in eighty-five per cent. of the patients, a most convincing argument in favor of circumcision in an adult whose prepuce cannot be easily and completely retracted. As our only hope of curing cancer lies in its early diagnosis and since carcinoma of the penis causes no marked symptoms until far advanced, the possibility of cancer should always be borne in mind in the case of an elderly man with phimosis and a foul discharge under the prepuce, even without the presence of induration. The prognosis is best when the inguinal glands are not involved, but it must be remembered that they may not be involved while the pelvic glands and organs are, so that a rectal examination should never be omitted. Barney urges early amputation of the penis at the pubes, with thorough cleaning out of the inguinal region, as the operation of choice, but he does not believe that total emasculation offers any greater hope of cure. He warns especially against the practice of leaving a dorsal flap, since in that case the main lymphatic trunks are not removed.

The Surgical Treatment of Pulmonary Embolism.

At the meeting of the Association of German Men of Science and Physicians held in Dresden last September Trendelenburg of Leipzig proposed a procedure that his hearers must have thought bordered on the impossible, namely, the operative treatment of pulmonary embolism. Starting with the fact that patients in whom this fatality occurs frequently do not succumb immediately, but may live for minutes or hours, Trendelenburg by work on animals and cadavers has attempted to devise a technique by which the pulmonary artery may be opened and the thrombus extracted from the main trunk or its larger branches. His first idea was to effect the removal of the clot by means of a special aspirating syringe, and he actually tried this in the case of a human subject, but failed, as the patient, a woman of sixty-two, suffering from carcinoma of the colon who suddenly went into collapse from pulmonary thrombosis, was found to have the complication of an old adherent pericardium, so that the exposure of the base of the heart was rendered very difficult. He now describes (*Zentralblatt für Chirurgie*, January 25, 1908) a somewhat different mode of procedure which he thinks ought to prove practically applicable. The heart is exposed by making a large osteoplastic flap of several ribs and the soft parts which is turned back so as to allow free access to the upper part of the organ. The pericardium is incised over the base of the heart, and a specially formed blunt hook somewhat resembling a metal catheter is passed around and behind the aorta and pulmonary artery. The vessels are pulled forward, the pulmonary artery is compressed with the finger by pressure against the hook, and is opened by a longitudinal incision a little higher up. The thrombus is then sought for by means of a polyp forceps or similar instrument, and if found is extracted. The wound in the vessel is closed with a long narrow clamp applied parallel to its long axis and the blood is again allowed to circulate. The cut edges are caused to protrude several millimeters when the clamp is applied, so that the incision can be sutured at ease while the instrument is in position. This operation has not yet been tried on the living human subject, but in an eight weeks old calf Trendelenburg was able to remove from the left branch of the pulmonary artery an artificial thrombus consisting of a piece of lung taken from another animal and introduced into the circulation through an incision in the jugular vein. The compression of the great vessels, which lasted something over a minute, did not seem to embarrass the heart's action and the animal recovered from the operation.

The Effect of Athletic Contests on the Health.

The point at which athletic contests cease to be beneficial or even commence to damage the organs of the participators is difficult to determine and has led to a great deal of discussion between the advocates of intensive exercise and more sober minded medical advisers. On numerous occasions the competitors in feats of endurance have been subjected to careful medical examination before and after the event, nearly always with the result that

a warning has been uttered against indiscriminate efforts to obtain the fame that is to be gained in this way. Early in last September the city of Kiel opened a new municipal athletic field and among the games with which the inauguration was celebrated were a walking contest of 100 kilometers (62½ miles) and a bicycle race of 187 kilometers (117 miles). Pfeiffer in the *Berliner klinische Wochenschrift*, January 20, 1903, describes the results of a medical examination of the contestants in these two events before and after. There was quite a difference in the condition of the finishers in the two races, for while a number of the walkers passed urine containing albumin and casts, had elevations of temperature that in some cases reached 39° C. (102.2° F.) and exhibited cardiac dilatation and irregularity or inequality in the pulse, the bicyclists showed no such evidences of the strain they had undergone. In both sets there was a moderate drop in blood pressure. These differences are probably due, however, to the fact that the bicyclists were in a better state of training than the walkers and more accustomed to endurance rides than the others were to forced marches. To the disappointment no doubt of faddists of various sorts it is also chronicled that although a considerable number of the contestants were vegetarians of one type or another or were believers in total abstinence, no noteworthy differences between their condition and that of less high minded competitors could be detected. The author's results emphasize the lesson that has already been learned under similar conditions, that while such feats of endurance may not necessarily be followed by directly injurious consequences they involve the risk of producing districts of lessened resistance which at a later time may invite serious organic disease, and that these hazards are especially great in youthful individuals.

Open Windows and Adenoids.

Commenting on the increased prevalence of adenoids, J. Louis Wallace contributes to a recent issue of the *Lancet* some new ideas as to the etiology of this affection. He notes that it is difficult to find evidence of many cases indicating the previous existence of adenoids among people of forty years of age and upwards, whereas it seems to be comparatively rare to find a family of children without at least one of its members having suffered from the disease. He took a census in a number of families whose habits he knew with regard to keeping the windows open in the sleeping rooms of their children. He found that of those who kept the windows shut at night there were five families, having twenty-six children in all, and not one of these twenty-six children had ever suffered from adenoids. While of five families, having nineteen children in all, who kept open windows at night throughout the year, eight of these children had suffered from adenoids sufficiently badly to have required operation. The writer is not disposed to lay too much emphasis on the showing of this particular census, but feels that a more complete knowledge on this possible effect of open windows on the growth of adenoids is worthy of further study. He seems, however, to be an adherent to the ancient opinion that the night air has a peculiar deleterious quality which the atmosphere in the daylight hours does not possess, and that it is of such a poisonous character that the air even of an hermetically closed room, laden with the exhalation from one or more bodies, is preferable.

News of the Week.

Colonel William C. Gorgas, Assistant Surgeon-General, U. S. A., who delivered the anniversary address at the New York Academy of Medicine on "The Sanitation of the Canal Zone" (see page 259), has been elected an honorary fellow of the Academy.

Civil Service Examination for Penitentiary Physician.—The State Civil Service Commission will hold an examination on March 7, 1908, for the position of physician, Onondaga County Penitentiary, salary about $480. Full information with application forms for this examination may be obtained by addressing Charles S. Fowler, Chief Examiner of the Commission, at Albany, N. Y.

Civil Service Examination.—The United States Civil Service Commission announces an examination on March 4, 1908, to secure eligibles from which to make certification to fill a vacancy in the position of acting assistant surgeon, Public Health and Marine-Hospital Service, for duty at St. John's River Quarantine Station, Mayport, Fla., at $125 per month, and vacancies requiring similar qualifications as they may occur. For the specific vacancy mentioned applicants must be expert in the diagnosis and treatment of yellow fever, and persons who are immune to that disease are preferred. Age limit, 20 years or over on the date of the examination. The medical certificate on the application form must be executed by an officer of the Public Health and Marine-Hospital Service, except when this requirement would work a hardship upon an applicant because of his distance from such officer he may have the certificate executed by any physician, in which event, however, he may be required to pass a physical examination before an officer of the Public Health and Marine-Hospital Service before appointment. Applicants must be competent physicians and surgeons and graduates of recognized medical colleges, and must furnish satisfactory evidence of their moral character and ability. This examination is open to all citizens of the United States who comply with the requirements. Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., for application Form 1312.

The Antituberculosis Movement in Chicago.—The annual meeting of the Chicago Tuberculosis Society was held January 28, 1908, when the following physicians were elected directors: Drs. George W. Webster, George F. Shears, William A. Evans, Charles L. Mix, Henry B. Favill, Frank Billings, E. A. Gray, Nathan S. Davis, Theodore B. Sachs, John A. Robison, Edwin W. Ryerson, Arnold C. Klebs, Ludvig Hektoen, and Robert H. Babcock. The Illinois Steel Company, South Chicago, through Dr. James Burry, surgeon-in-chief, has offered to give to the Chicago Tuberculosis Institute one of its buildings, rent free, for the use of its dispensary and local headquarters. The Open-Air Sanatorium for Jewish Consumptives has been incorporated, to establish a sanatorium near Chicago, to consist of an administration building and smaller buildings or tents for patients.

Tuberculosis Exhibit.—The tuberculosis exhibition, which has been held in the Metropolitan Life Building on Twenty-third street, has had more than 100,000 visitors during a little more than a month. Next week it is to be moved to the Cathedral School and early in March it will be transferred to the Natural History Museum.

Moritz Schmidt's Will.—An instance of the thoroughly scientific spirit animating the late Moritz Schmidt, the well-known laryngologist, who died a few weeks ago, is afforded by a provision of his will. As he considered that through his coming into close contact with so many tuberculous patients the condition of his organs might throw light on the question of the direct transmission of this disease he left directions that an autopsy be performed with especial reference to this point. This was done and no signs of tuberculosis were discovered.

Typhoid Epidemics.—An epidemic of typhoid fever is causing considerable alarm in Boswell, a Pennsylvania mining town with a population of 1,000. Over 175 cases have already been discovered. An epidemic of smaller proportions has also been reported from Peekskill, N. Y. In both instances the water supply is thought to be the source of infection.

Diphtheria in the Rahway Reformatory.—Over 200 cases of diphtheria have been reported in the Rahway Reformatory and not even the officers are allowed to leave the institution. It is thought that the epidemic is under control, as no new cases have been discovered for several days.

Diphtheria Death in Christian Science Family.—The nine year old daughter of a Christian Scientist living in Danville, Ill., died last week of diphtheria, and as the health officer refused to issue a burial permit an inquest was held at which the jury declared the parents responsible for the child's death. Four other children, an infant of two years, a daughter of twelve, and two sons of fourteen and sixteen years, respectively, are also dangerously ill with the same disease.

Vital Statistics of New York State.—During 1907 the average birth rate for the State was 20.8 per 1,000. Five cities had a rate of over 25, Dunkirk coming first with 35.9, New York City having 29.3 and New Rochelle 28.3. The total number of births reported was 195,735, divided as follows: Males, 100,495; females, 95,187; sex not stated, 53. The white babies numbered 193,059, negroes 2,625, Indian 26, and Chinese 25. Estimating the population at 8,386,000, the death rate was 17.5. Of the total deaths, 147,442, tuberculosis of the lungs was responsible for 14,406, an increase of 379 over 1906 and 802 over the average for five years, and the greatest number for any one disease, while heart disease came second with 17,072, and pneumonia third with 10,990. Leprosy caused one death. From tuberculosis of other organs than the lungs there were 2,164 deaths. Typhoid fever deaths increased over the previous year by 100, making a total of 1,668. The mortality from measles was decreased from a five years' average of 1,035 and the total in 1906 of 1,369 to 995 in 1907. Scarlet fever, on the other hand, was more fatal, the total in 1907 being 1,029, while in 1906 it was only 690, and the five years' average was 976. There is a gain of about 100 in the deaths from diphtheria over those of last year, 2,600 deaths being due to this cause. The five years' average was 2,784. There were 2,372 deaths from influenza and 483 from erysipelas. Only 225 deaths from cerebrospinal meningitis were reported; the year before the total was 1,178. Cancer deaths also show an increase, last year's totaling 6,400, an increase of 727 over the five years' average. Diseases of the nervous system were responsible for 14,468, and those of the circulatory system for 16,893 deaths. The deaths under 1 year were 27,957; from 1 to 5 years, 12,142; from 5 to 10 years, 3,249; from 10 to 20 years, 5,206; from 20 to 40 years, 24,830; from 40 to 60 years, 29,539; from 60 to 80 years, 34,516; and over 80 years, 9,838. Of males, 76,904 died; of females, 67,476.

Caring for the Insane.—In an address recently delivered before the Chicago Society of Anthropology on the Duty and Function of the State University in the Legislative and Administrative Affairs of the State, Dr. Bayard Holmes said that the State University should provide professors and students for work in the asylums. He said that "there is one person in every five hundred in Illinois crazy and shut up. The proportion of crazy persons is larger than that, but we are not all shut up yet." His leading idea was that the university should be auxiliary to the legislative and administrative laws of the State, especially in reference to its charitable institutions. Every professor is, or should be, a master in his line, and when any bill affecting the State wards is before the legislature, the university professor best informed in the matter should be called in to aid in framing it.

The International Vivisection Union is an organization with offices at 50 East Twenty-ninth street, which has been incorporated for the purpose of investigating animal experimentation.

Smoking in Great Britain.—The British authorities propose to make smoking illegal under the age of sixteen and to prohibit the sale of cigarettes and tobacco to children under that age. Tobacconists who violate the law will be subject to fines and parents who permit children to smoke will be liable to prosecution.

Busts of Dr. William E. Quine and Dr. Robert L. Rea were presented to the College of Physicians and Surgeons in Chicago on February 1. Dr. A. H. Ferguson made the introductory address. The bust of Dr. Rea was presented by Dr. Frank Billings and accepted for the College by Dr. Oscar A. King. Dr. William Allen Pusey presented the bust of Dr. Quine and it was accepted for the college by Dr. Daniel A. K. Steele.

The New York Psychiatrical Society.—The first of a series of public lectures will be delivered by Dr. Pearce Bailey, Saturday, February 15, 1908, at the Academy of Medicine, at 8:30 P. M., on "Alcoholism."

The Sisters of St. Augustine, who for thirteen centuries have served as nurses in the Hôtel-Dieu of Paris, have finally been obliged to leave the hospital in consequence of the recent anti-clerical measures. On their departure from the building they were accompanied by thousands of persons assembled to testify to the gratitude in which they were held and numerous members of the municipal council as well as the director of the Assistance Publique expressed their esteem and regret in person.

The Late Dr. Henry P. Loomis.—The following resolutions were adopted by the Medical Board of Bellevue Hospital at its meeting held on February 1, 1908:

"The Medical Board records with sorrow the death on December 22, 1907, of its late colleague, Dr. Henry Patterson Loomis, who for twenty years was actively connected with the Visiting Staff of Bellevue Hospital. During this long period of service Dr. Loomis was always zealous in promoting the highest interests of the hospital, both ethical and scientific. He several times served as President of the Medical Board and was an efficient member of its various committees. His work as a clinical teacher did much to broaden the influence

of the institution, and, among the many researches which he conducted, his contributions to the study of tuberculosis are especially commendable."

It was moved that this expression of appreciation of the faithful work of Dr. Loomis for the hospital be recorded upon the minutes of the Medical Board, and that copies be sent to his family and to the Trustees of the institution.

Obituary Notes.—Dr. Fayette E. Schley of this city died suddenly of heart disease on February 8 at the age of fifty years. He was born in Canandaigua and was graduated from the Albany Medical College in 1881. He immediately began practice in this city and continued in active work until about two years ago, when he retired.

Dr. William Dana Gross of Philadelphia died on February 8, at the age of forty-seven years, of septicemia, contracted at an obstetrical operation. He was born in Philadelphia and received his medical degree from the University of Pennsylvania.

Dr. Washington West of St. Louis, Mo., died on January 31 of heart disease at the age of sixty-one years. He was born near Belleville, Ill., and was graduated from the medical department of Washington University in 1868. For some years he was assistant surgeon in the U. S. Army and was stationed in the Sioux Indian reservation in Dakota.

Dr. Charles A. Wilson of San Antonio, Tex., died on January 26 at the age of fifty years. He was born in Warren, O., and was graduated from the Cleveland Homeopathic Medical College in 1883. After practising for a time in Ann Arbor he went to Pittsburg, where he remained until failing health compelled his removal to San Antonio in 1892.

Dr. Charles C. Holcombe of Lee, Mass., died on February 2 at the age of seventy-eight years. He was born in Granville, and was graduated from Yale Medical School in 1850. He practised for a time in Granville and in 1853 removed to Lee. He was the first medical examiner of the Middle Berkshire District, holding the post for almost twenty-five years. In 1899 he was made president of the Lee National Bank, and he had served several terms as president of the Berkshire Medical Society.

Obituary.

HENRY NEWTON HEINEMAN, M.D.

BAD NAUHEIM.

Dr. H. Newton Heineman, who died suddenly of heart disease on February 11 in Paris, was well known to the older members of the profession in New York, having lived and practised in this city for many years. He was not quite sixty years of age, and was a graduate of the College of Physicians and Surgeons in the class of 1874. He practised here for about twenty years, being at one time a visiting physician at Mt. Sinai Hospital. Ten years ago he went to Germany, passing the Staats-Examen and gaining the right to practise despite the opposition of some of his future colleagues. He settled in Nauheim and became favorably known to Americans for his success in the special treatment of heart disease by the methods in vogue at that watering place. His winters were passed in Paris. Dr. Heineman was recognized by his professional brethren both here and in Germany as a diagnostician of much acumen and also as a successful therapeutist. In social life his cordiality and sincerity won for him a large circle of warm and enduring friends.

THE SIXTH HARVEY SOCIETY LECTURE.

The sixth of the present series of lectures given under the auspices of the Harvey Society was delivered at the Academy of Medicine on Saturday, February 8, in the presence of a large audience. The speaker was Professor Joseph Jastrow of the University of Wisconsin and the subject "Subconsciousness."

Professor Jastrow began by pointing out that the possession of a real consciousness had formerly been denied the lower animals. In the philosophy of Descartes, animals behaved very much like machines, and even Huxley held views resembling these. At the present time, however, the conceptions regarding consciousness had undergone considerable change, and while the subject presented many difficulties, it was impossible for the psychologist to escape defining and studying the nature of consciousness.

The speaker then discussed the utility of consciousness, and remarked that in a healthy individual the attention went where it was needed. It was not always necessary, however, for the attention to be directed. In fact, normal conditions required that the consciousness slumber, as it were. It was impossible for anyone to continue for any considerable time focusing his attention along a given line. But although we might not really have the sense of awareness, it could be shown that the consciousness did not really slumber. It continued to perform a whole host of actions almost without our knowledge. But there were stages between this acute awareness and the subconscious actions, and we all were familiar with this stage, commonly spoken of as reverie, day dreaming, or in slang parlance, "pipe dreaming." This kind of thinking was the easiest because it lacked all restraint. It was surprising to find the amount of this subconscious material in our daily mental activities. To be sure, it did not always come to the surface, being controlled largely by the higher, directing consciousness. Our true self, Professor Jastrow said, was made up not only of our ordinary conscious selves, but of the sum of all our subconscious selves as well. In fact, the latter was the most free from restraint and was the self which we most often revealed to our intimates.

In the investigation of the subconsciousness the study of various pathological states had proven of enormous value. The speaker illustrated this by a case of hysteria in a young woman. She complained of complete anesthesia of the hand. On asking her to concentrate her attention on a number, and then gently tapping her hand, say seven times, she would be surprised to be told that she had been thinking of the number seven. As a matter of fact, her subconsciousness had received the impression made by the tapping on the supposedly anesthetic hand. Similar results could be obtained by examining subjects during hypnosis. It was interesting to note that in this state the subjects still maintained a partial orientation with their surroundings. The actions performed by a person in the hypnotic state did not make an impression on the real consciousness, and on merging from the hypnosis there was no recollection of those actions.

It was possible to inhibit the higher consciousness by means of drugs, such as ether or nitrous oxide. The loss of this restraint created a feeling of seeing deeper than ever before. The speaker recited the experiences of Holmes, Sir William Ramsay, and others, with experiments on themselves. They all felt as though they were seeing

into the real world for the first time. Now at last they had learned real truth. Holmes had even felt the impulse to save a glimpse of this real truth, and had written it down. On emerging from the effects of the anesthetic, he discovered that his writing consisted of a few very commonplace sentences.

Professor Jastrow then described the conditions in a normal individual, stating that temperament was an important factor in determining the degree to which the subconsciousness manifests itself. Most interesting were the cases of handicapped, altered, divided, or distorted consciousness. A careful study of these cases had shed considerable light on the action of the mind. One of the famous cases of this kind was that of Helène Smith, a shop-girl of Geneva, Switzerland. This young woman had gradually elaborated a marked alter ego. She gave seances, in which she appeared in either of three rôles. The best developed of her dramas was a Martian one. In this she had gradually constructed a Martian language, which, while it was at first entirely unintelligible, had been found to have a syntax closely resembling the French, her mother tongue. Her other rôles were, respectively, a Persian one, and one in which she took the part of Marie Antoinette. While in the trance she still maintained a partial orientation with her surroundings. Once, in the rôle of Marie Antoinette, she had smoked a cigarette, an act which was objected to as being out of keeping with the character. The act had never been repeated.

The speaker then gave a short sketch of the wonderful case of multiple personality reported by Professor Prince, the case of Miss Beecham. This young woman was a college girl, twenty-three years old, and of a highly nervous temperament. Her personality changed frequently, often from hour to hour, three characters being involved. Two of these had no knowledge of the other personalities. The third, however, knew all about the other two, and, curiously, was very antagonistic to them. In her character of Miss Beecham she was fearfully afraid of reptiles, mice, etc. Yet in her third character, Sally, she delighted to prepare all kinds of horrible surprises with such animals for her other self. Once or twice Miss Beecham had penetrated in her mind to the doings of Sally, but this was exceptional. On the other hand, Sally always knew every thought that Miss Beecham had. Careful study of the case in the hypnotic state had shown that "Sally" was the subconscious self of Miss Beecham. By a great deal of very painstaking effort it had been possible gradually to force the "normal" self in the ascendency, and so effect a cure. In connection with these cases, it was to be remembered that the conditions were dream *states* in normal individuals, but dream *selves* in abnormal ones.

Professor Jastrow also referred briefly to the case of Rev. Mr. Hanna, who after an accident had lost a completely developed personality, and had to begin all over developing a new one. In certain dreams which this patient had, incidents and scenes from this former personality frequently made their appearance. These, stored up by his subconsciousness, were not accessible at other times. In the case of Brown, reported by Professor James, the patient became his former self during hypnosis. By this means his lost personality had gradually been restored.

It was evident from all that had been said that the states and conceptions of subconscious functions must be derived from normal outside life. We should conceive that there were two states of mind, one an active, controlling state, the other a dreaming, wandering one. Both were important. It was necessary at times to relax from the discipline of the former, otherwise nervous exhaustion, insomnia, and other forms of breakdown followed. Hysteria was very instructive for the psychologist. In this mental and emotional instability dominated; the directing side of the consciousness was weak. It was possible to strengthen this, however, and this was the function of the psychologist. Medical science would have to give mental therapeutics more recognition than it had in the past. The speaker therefore regarded it as a good omen that the Harvey Society had asked a psychologist to address this audience.

The next lecture of the series will be delivered on Saturday, February 22, by Professor Otto Folin of Harvard University, the subject being "Problems of Chemistry in Hospital Practice."

(From Our Special Correspondent.)

SANATORIA—ACTION FOR LIBEL—CEREBRAL HEMORRHAGE AND ECLAMPSIA—ANOTHER PARASITE OF MAN—ANKYLOSTOMIASIS—DIPLOMAS FOR WOMEN—DR. NEWSHOLME SUCCEEDS M. POWER, C.B.—ITEMS.

LONDON, January 24, 1908.

YESTERDAY a report on sanatoria was issued by the Local Government Board. It is a bulky volume of 670 pages, written by Dr. Thos. Bulstrode in continuation of the report of the Medical Officer on Tuberculosis for 1905-6. It is fully illustrated by charts and diagrams, and deals with various aspects of the tuberculosis question as well as with the points of importance concerning sanatoria. Thus the declining death rate from consumption, the communicability of the disease, its duration before the sanatorium treatment became established, statistics of those treated as to immediate and later results, and as to the early or advanced condition of the patients, the need of after-care, and many other points are considered by Dr. Bulstrode. Though it is not possible, or perhaps desirable, to lay down definite conclusions from the evidence at present available, there is little doubt that the immediate result to individual consumptives is in the main encouraging, and Dr. Bulstrode confirms the general view that the best results are seen in early cases, and that when improvement occurs in advanced cases it is commonly less durable, although remarkable temporary amendment is often observed in such patients. Respecting "after-results," Dr. Bulstrode is cautious—not to say hesitant. The statistics do not give him, save in exceptional instances, data as complete as is requisite, immediate and after-results being too often confused, while the latter are apt to be affected by the method of selection of cases for admission and by the after-care available for patients after discharge.

In reference to the vexed question of notification, Dr. Bulstrode does not consider that the time has arrived for judging of its value in the light of phthisis death rates, but he notes the fall in these rates which has been going on for many years throughout this country has not been obviously accelerated in towns which have adopted some form of notification. The attention drawn to phthisis of late has given rise to an impression among the public that the disease is increasing, whereas it has undergone a phenomenal decline which, if continued for years, might result in its total extinction.

I am sorry to say the *Lancet* has lost the action I mentioned as pending last week and has been cast in heavy damages. Quacks are, of course, in high glee to find that a denunciation of secret proprietary preparations may expose a journal to an action for libel. The *Lancet's* defence was fair comment on a matter of public interest, and further that the indiscriminate distribution of dangerous poisons is indefensible. It was shown and not denied that the medicine contained atropine and cocaine; and the president of the College of Physicians, supported by Sir L. Brunton, Professor Pepper, and other distinguished authorities, testified

that these medicines ought not to be used indiscriminately. But, of course, as I reported, there were practitioners ready to come forward and declare that the quantity of the poisons was too small to be dangerous and that they had recommended the remedy. Plaintiff's counsel argued that to impute fraud was to attack a person's character and had a cheap jibe at the profession which could not cure a disease, but attacked his client for curing it. The judge ruled that if the jury found that the attack was on the man—not on the system—plaintiff was entitled to a verdict, as the defendant had not pleaded justification. In view of this ruling, I could wish a plea of justification had been put in, though of course the defence had to be under the advice of counsel. It would seem possible to convince plain business men, such as jurymen mostly are, that a trade consisting of the sale of a specific for eight shillings an ounce, which would cost the seller two or threepence, was not a just commercial transaction.

Cerebral hemorrhage as the cause of death in puerperal eclampsia has been recognized for a long time. The occurrence was discussed at the Royal Society of Medicine (Obstetric Section) in connection with a paper by Drs. Norman Carver and J. S. Fairbairn, who related a case of an unconscious patient with a history of edema and albuminuria. She was deeply comatose with Cheyne-Stokes respiration. Rapid dilatation of the cervix was done, and a fetus of five to six months extracted. She died a few hours later, and at the post mortem an extensive hemorrhage into the pons varolii was found. The authors considered the case as primarily one of eclampsia, and quoted four analogous cases.

Dr. Herbert Spencer (President) had not met with a case of hemorrhage into the pons, but had seen two into the substance of the brain, one at a post mortem, the other with recovery. He thought apoplexy a well known cause, and the intravenous injection of saline solution risky.

Dr. MacNaughton-Jones considered that weak doses of pilocarpine afforded the best means of controlling the increase of blood pressure in the threatening hemorrhage and further were of use in checking the convulsions. If necessary its full physiological action could be neutralized by atropine (1-100 grain). He had seen eclampsia fatal as early as the fourth month.

Dr. Lionel Smith had seen three cases of cerebral hemorrhage complicating eclampsia, all confirmed at post mortem.

Dr. Amand Routh had not seen a post mortem of such a case. He doubted if saline infusion should be given on account of the increase of arterial pressure. Pilocarpine was fraught with danger in the usual doses. It ought not to be given where apoplectic symptoms or coma were present. He had seen patients suffocated by the enormous quantity of ropy mucous secretion it provoked.

Dr. Rayner had a fatal case in a patient in her eighth month of her third pregnancy. The convulsions were frequent, more marked on the right side, pupils unequal, urine albuminous, the coma deepened with death in a few hours. Extensive hemorrhage into the corpus striatum and optic thalamus was found post mortem.

Dr. Hodgson thought the practical lesson was to empty the uterus in all cases of eclampsia in pregnant women. He had done this in six cases and all recovered—five rapidly. In one slight convulsions persisted for five days, but she was well after a single injection of pilocarpine.

Dr. Fairbairn, in reply, said they had not collected all cases of apoplexy, but only those of hemorrhage into the pons or base of the brain, without unilateral symptoms suggesting apoplexy. Large cerebral hemorrhages were not frequent in eclampsia, as shown by statistics. The cases he and Dr. Carver submitted were undoubtedly rare. Of course the possibility of a deeply comatose and cyanotic eclamptic patient having also a cerebral hemorrhage should not be forgotten, especially in giving a prognosis.

Dr. Leiper has described a new intestinal parasite of man at the Society of Tropical Medicine. This *Physaloptera morcleus* differs from the *P. caucasica* by its greater size in the disposition of the papillæ of the male bursa and the contrast in the size of the spicules; in the female in the position of the vulva and smallness of the egg. An additional pair of teeth and two pairs of papillæ are also seen.

At the same meeting Dr. T. F. Macdonald related his experiences of ankylostomiasis in Australia. In the Johnstone district a jungle of scrub 50 miles square with a rainfall of 200 inches and frost unknown, the conditions were ideal for the incubation of parasites, and there ankylostoma duodenale spread from family to family. Recently the Federal Government has voted a sum for establishing a research institute in Townsville (in this district).

As to the disease, he said in children there was an extraordinary appetite for earth-eating—not a casual impulse, but an irresistible craving. Babies would pick dirt from seams in the floor or from boots left uncleaned; older children preferred to suck stones rather than sweets; adults craved for pickles, curries, and alcohol. He also observed psychopathological symptoms characterized by what he termed a "spectrum of deeper and deeper immoral qualities" growing with the progress of the disease. It was difficult to determine whether there were moral and mental changes parallel to physical abnormal appetites or accidental aberrations. He believed they were as definite symptoms of positive nerve poisoning as anemia was of blood destruction. Schoolmasters had consulted him as to the demoralization among children. He thought two factors were necessary to produce these effects, viz., a weakened physiology of the victim and an exciting nerve toxin. Thymol was the treatment for the individual, but how was the disease to be stamped out in a community? He had treated households with thymol and regarded as "contacts" all under one roof, but new centers continually arose.

Dr. Sandwith said thymol was not safe for the aged or the very young. It was better to give eucalyptus (10 minims of oil and 45 of chloroform) in 10 drams of castor oil.

Dr. Elliott found it better to prepare the patient with podophyllin before the thymol.

Sir Patrick Manson, President, spoke favorably of the eucalyptus, castor oil, and chloroform, and mentioned that he also noticed the development of immorality in children who were victims of the disease.

Dr. Macdonald, in reply, agreed that thymol was dangerous and welcomed the statements as to the value of eucalyptus.

While the College of Surgeons is preparing to take a plebiscite of its members as to the admission of women, the College of Physicians has taken a step in that direction. After discussing the proposal, it was resolved on Friday last to admit them to the examinations. This, however, does not settle the question altogether, as the license is only given in conjunction with the College of Surgeons, which could therefore so far make the resolution of no effect, and this double qualification is a general practitioner's one. On the other hand, the membership is a physician's diploma, and candidates holding a university degree are eligible, so that the College of Physicians is unhampered as to this and its resolution can take effect. As the fee for admission is 30 guineas, not every female university graduate will take it, but a few will no doubt be willing to contribute that much for the pleasure of becoming M.R.C.P., especially as that practically carries the privilege of being eligible for appointment on the medical side of hospitals—and the ladies will certainly next demand such positions. The Fellowship is a matter of election, and women are not likely to lack in the art of securing votes.

Dr. Arthur Newsholme, F.R.C.P., has been appointed Medical Officer to the Local Government Board in succession to Mr. W. H. Power, C.B., F.R.S. You will recognize the name of Dr. Newsholme as of one who has attained a distinguishable position in the public service and as an authority on all sanitary questions. Mr. Power, whose ability has so long been conspicuous, carries into his retirement the hearty good wishes of his professional brethren.

Professor W. J. Simpson, who has had great experience of plague in India and other parts, has been appointed to go to the Gold Coast to deal with the outbreak at Accra, and left on Saturday, accompanied by Dr. J. A. Haran of the East African Medical Service, who has also had experience of plague in the protectorate.

The Hospital Saturday Fund collections for 1907 reached £27,168, and at a meeting of the delegates on Saturday it was resolved that £24,708 be distributed among the 200 participating medical charities.

Mr. H. A. Wills has promised £100,000 towards the endowment of a university for Bristol, provided a charter be obtained within two years.

Microorganisms on Coins.—A recent French investigator states that the average Parisian copper has 11,000 bacteria; gold pieces from 1,600 to 3,500; while silver coins have only from 450 to 2,100.

OUR BERLIN LETTER.

(From Our Special Correspondent)

HYDROCHLORIC ACID TREATMENT OF GOUT—INFANT FEEDING—MALIGNANT GROWTHS—THE MATERIAL POSITION OF PHYSICIANS.

BERLIN, January [illegible], 1908.

In the Berlin Medical Society Falkenstein presented a paper entitled "A Retrospect of Five Years of Treatment with Hydrochloric Acid in Gout." According to the author, gout is an hereditary disease involving the glands of the gastric mucosa which atrophy to some extent, and therefore are unable to supply a sufficient quantity of hydrochloric acid. The patients accordingly must receive comparatively large amounts of the acid for months or years. The acid deprives the tissues of alkali and in this way prevents uric acid from being precipitated as monosodium urate. The speaker said he had treated 390 gouty individuals by this method and in one-third of the cases prompt relief had resulted, in one-third there was improvement, while in the remainder the treatment was without effect. It is unnecessary, according to this theory, to insist on a nuclein-free diet.

At the previous session the problem of infant feeding was discussed by L. Langstein. He first compared the composition of cow's milk with that of human milk, pointing out that, as was well known, the former had a larger albumin content, whereas the latter was richer in sugar. Little attention had heretofore been paid to the fact that cow's milk is about three times as rich in salts as human milk, and Biedert's assumption that the crux of the entire question lies in the differences in the amount of albumin of the two milks was no longer to be regarded as tenable. In infants nourished with cow's milk, flocculent masses were frequently found in the stools and considered as curds. It had been found, however, that these masses were composed of fat derivatives, and the statement that the high albumin content of cow's milk was injurious to the infant was no longer justified. The more recent biological laws were also applicable to infant feeding. The child fed on breast milk received homogeneous albumin, but that of cow's milk was heterogeneous and could give rise to a precipitin reaction; that is, it resembled a poison, and the conclusion had been drawn that cow's milk was toxic. Homogeneous albumin could be absorbed without difficulty from the gastrointestinal canal of the infant, whereas the foreign proteid could be broken down in the intestines only as the result of the activity of the intestinal cells. It had been shown, however, by Heubner's disciples that the homogeneous albumin also first required to be broken down and therefore the toxicity of the heterogeneous albumin could no longer be maintained. There was now no more room for doubt in regard to the toxicity of the fat in cow's milk. White and curdy stools were signs of disorder that were best combated by diminution in the fat and increase in the carbohydrates, and in this connection buttermilk was especially valuable. Finkel had shown that overfeeding with carbohydrates could cause fever in infants and in general it might be said that an excess was injurious. The speaker considered that boiling the milk did not interfere with the nutrition of the infant.

At the same meeting Lewin described experimental contributions to the morphology and biology of malignant growths. While heretofore experimenters had concerned themselves chiefly with mouse tumors, he had succeeded in investigating a primary adenocarcinoma of the breast of the rat. On transplantation this tumor caused the development of cancroids and spindle and round-celled sarcomas. Clinically the tumor manifested all the signs of human carcinoma. When parts of the growth were transferred to the abdominal cavity of a rat new growths of the abdominal organs and ascites resulted, the animals dying of cachexia. Young animals were particularly susceptible to the inoculations. In both carcinoma and sarcoma there was a congenital and acquired immunity. If the tumor began to retrogress in an animal after a preliminary period of growth immunity followed. The same thing was true in the animals inoculated without results. Lewin found that in rats well marked immunity followed the injection of normal serum, as Bashford had already shown in mice. It was possible to render mice resistant to very virulent mouse cancers by previous treatment with rat tumors and to protect the rats against rat carcinoma by inoculation with mouse tumors.

In the Society of Social Medicine and Hygiene Leo read a paper on the material position of mental workers. While this did not possess any direct bearing on practical medicine, a short summary of his statements may be of interest, as he discussed particularly the condition of the medical profession in Germany. For example, taking into consideration the greater demand in time and money required in his education, the income of a physician was not very much higher in proportion than that of the mechanic. The tax lists of Berlin showed the following in regard to the incomes of physicians during the year 1905: 25 per cent. of the physicians had incomes of less than 3,000 marks, 17 per cent. from 3,000 to 5,000 marks, and only 50 per cent. had more than 5,000 marks annually. In Austria the conditions were still worse. The German physicians had begun to take action against this state of affairs by the formation in the year 1901 of the Leipsiger Association of German Physicians for the Preservation of Material Interests, generally spoken of as the Leipsiger Association. The object of this organization was to unite the physicians in an effort to improve their economic position and particularly to assist those physicians who were obliged to make sacrifices in the combat against the lodges. This object was attained through the establishment of a relief fund, a registration bureau, through the collection of statistics in regard to the relation between physicians and lodges, and the appointment of commissions to conduct negotiations with the lodges. The physicians pledged themselves in case of dissension between lodges and the Leipsiger Association not to accept any position with such lodges. The association at present had 124 sections and in the past year provided positions for 3,374 physicians. Of the 32,000 medical men in Germany, about 20,000 were members of the association. Strikes and boycotts were resorted to just as was done by the labor unions. The results were already noteworthy and the association believed that it had through its efforts increased the annual incomes of German physicians by about 8,000,000 marks.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 30, 1908.

An Insidious Type of Nontuberculous Pyelonephritis.—Two case histories are presented by A. L. Chute. The type referred to does not present the usual renal pain, kidney tenderness, temperature. Symptoms are more apt to be solely those of a cystitis. This was true in the two cases presented. In the first case it was supposed that the removal of infected tubes and uterus would relieve the cystitis and valuable time was lost. This type represents a group in which infection with a nontuberculous organism either ascends to the kidney or if it does not ascend begins as a surface infection of the kidney pelvis and leads to a slow erosion of secreting tissue. As the symptoms of cystitis persist, but without the great increase in frequency and pain that is often seen in tuberculous cystitis, the patient gets accustomed to the discomfort, and the process extends insidiously, in that there is the addition of no new or startling symptoms until the renal tissue is destroyed to such a degree that the patient has a deficient power of elimination. The duration of this insidious progression may be several years. The failure of the power of elimination and the appearance of symptoms that mark the true character of the process occurs only when both kidneys are involved to such an extent that they have a combined power of elimination that is less than that of one normal organ. At this time it will be too late to attempt operative measures successfully. We rarely have in these cases the usual renal pain, tenderness and enlargement. Of great significance is the presence of casts in the urine. The employment of the cystoscope is the only reliable means of differential diagnosis. The author finally declares that in cases that are apparently chronic cystitis, but which persist without evident cause, we should consider that the burden of proving that the condition is *not* renal rests on the physician. Early treatment by means of drainage is probably our most efficient means of treatment.

Adenoids and Tonsils.—H. G. Longworthy considers this subject from the standpoint of the general practitioner and with special reference to an examination of the throat in chronic systemic infections and a consideration of the question of status lymphaticus in these cases. The work of investigation in the matter of the tonsils as portals of infection is briefly reviewed. The author does not believe that the question as to whether in a particular patient the throat is a point of entrance for joint infections

can be truthfully answered. It is wise to thoroughly extirpate enlarged tonsils if they are present and thus replace a structure of at least lessened resistance by a sound wall of tissue. Undoubtedly a tonsil which becomes infected on slight provocation constantly menaces the patient with lesions which range all the way from a lacunar tonsillitis to endocarditis and pulmonary tuberculosis. Adenoids undoubtedly are responsible for many of the febrile attacks of childhood. They may become suddenly inflamed, cause earaches from temporary closure of the Eustachian tubes, and are more common than even the laryngologist has supposed.

New York Medical Journal, February 1, 1908.

Noma.—The results of a bacteriological study of seven cases are presented by R. C. Rosenberger, who summarizes some of the recent literature on the subject. He is of the opinion that this affection is due to a symbiosis of a number of bacteria, the principal ones of which are the symbiotic organisms of Vincent. It is well known that the fusiform bacillus of Vincent is found in healthy mouths, and it is also a well known fact that the spirillum of Vincent is also seen in spreads from healthy persons. In the ulceromembranous stomatitis of Vincent both of these bacteria are present and generally in abundance. The reasons advanced by the author to substantiate his view are that the disease is first evidenced by a membranous or ulcerative process; that in this stage the fusiform bacillus and the spirillum of Vincent are present in great numbers; later, as the process goes on to gangrene, other organisms like the diphtheria-like organism, streptococci, or other microorganisms, make their appearance, and from this latter invasion toxemia develops, and the disease goes on to a fatal termination. These facts are borne out by the study of these cases and the bacteriological findings.

Tuberculosis Among Medical Students and Its Prevention.—According to W. J. Wile, the medical student is exposed to tuberculosis in the clinical laboratory, the postmortem room, and the hospital ward. Exposure in the former is probably a nominal one, as the ordinary technical routine taught sufficiently obviates danger from this source. The student should receive special instruction in regard to the matter at the commencement of his course. He should be cautioned against overwork, underexercise and overstimulation. He should have his attention called to the widespread incidence of slight tuberculous infection among the healthy. Finally, proper hygiene, which is after all the best prophylaxis, should be strongly emphasized. Unfortunately in large cities, where clinical opportunities are good, proper hygienic surroundings for the student are not equally good. He should be urged, however, to spend at least one hour each day in the open air, to retire and to rise at regular hours, the morning to be well initiated by the cold tub or sponge. Using his mind constantly, the student should, above all things, have good food, and it is indeed poor economy to frequent, as many of the students do, the cheap boarding houses usually found in the proximity of the hospital or college. House infection is without doubt a factor in some cases. The author lays down certain practical rules in regard to personal habits in the ward and laboratory and believes that their observance will greatly lessen the incidence of the disease among this special class of patients.

Anesthesia by Nitrous Oxide, Nitrous Oxide and Oxygen, Nitrous Oxide and Ether, Chloroform and Oxygen, and Ether Administered per Rectum.—P. L. Breton summarizes his experience on over 300 cases and figures an apparatus for the administration of nitrous oxide and oxygen for prolonged anesthesia. Nitrous oxide was given alone 18 times, nitrous oxide and oxygen 15 times, and ether by rectum 15 times. There was a large proportion of throat cases, 114 in all, the majority being given nitrous oxide and ether for the excision of tonsils and adenoids. In many of the cases the choice of the anesthetic and its administration were of importance on account of such conditions as endocarditis, myocarditis, nephritis, diabetes, empyema, a preceding pneumonia, anemia, etc. In one instance, that of a man of 45 years with an irreducible hernia, death resulted from the anesthetic. The patient had had since youth a rapid pulse, always over 100, and usually running 106 to 110. There was some increased tension. The heart sounds were apparently normal. The urine had showed some time previously albumin and casts, but nephritis at the time was absent. An asthmatic condition had existed for years, causing the patient to sleep at night in a chair until early morning, when it was possible for him to lie down. While asleep he showed Cheyne-Stokes breathing, there being in the interval a cessation of respiration for thirty seconds. Nitrous oxide and ether were chosen, and the patient was fortified by extra feeding, strychnine, and strophanthus the night and the morning before operation. From the beginning of the anesthesia the man did not relax well, but remained rigid and somewhat cyanotic. Eight minutes after the nitrous oxide was started and four minutes after the operation had begun, the heart suddenly stopped and deep cyanosis and dilatation of the pupils appeared. Artificial respiration, cardiac massage, and stimulants were of no avail. Ten gallons of nitrous oxide and three drachms of ether had been used. The indications for the respective choice of the various sequences mentioned in the title are carefully given.

Carcinomatosis of the Meninges.—D. J. McCarthy and M. K. Meyers give the details of a case, adding considerations on the diagnosis of multiple carcinomatosis, tuberculosis of the nervous system, disseminated syphilis, and multiple sclerosis. A careful search through medical literature has revealed only 11 cases. These are commented on by the authors, who then present their own case, the patient being a colored woman of 38 years, who died after being under observation some six weeks and whose symptoms had begun some three months before she came under observation with pain in the right elbow and hand and temporal and occipital headaches. Two days later the pain extended to the left hand. Several days later she complained of pain in the lumbar region and in both lower extremities. There was persistent cough with pain in the chest and back. Motion and sensation were normal. The right pupil reacted sluggishly to light. The right knee jerk was absent; the left knee jerk was present, but diminished. The Achilles jerk was present on both sides and decreased. There was no ankle clonus and no Babinski reflex. There was flexion of all the toes to plantar irritation. The superficial abdominal reflexes were normal. The biceps and triceps jerk of both upper extremities were exaggerated. Examination of the chest revealed impaired resonance over the left chest posteriorly, below the angle of the scapula. Over this area there was bronchovesicular breathing and moist râles, more marked on expiration. Vocal and tactile fremitus were increased over the same area. The patient gradually developed palsies of the ocular muscles, and died. Autopsy revealed chronic pleurisy, hemorrhagic infarct of the lung, carcinoma (primary) of the lung, chronic diffuse nephritis, secondary carcimona of the liver, and primary carcimona of the pancreas. A cavity was found in the left lung—upper lobe. Gross examination of the brain revealed its entire surface covered with minute white areas varying in size from a pin point to a pin head. These areas were most frequent along the course of the blood-vessels, and occurred in scattered points over the entire meninges. They were most marked and occurred in the greatest numbers over the base of the brain, and especially in the interpeduncular spaces. The same condition was present over the spinal meninges, and most marked over the cervical enlargement. There was a tumor mass the size of a split pea on the tenth dorsal root. The second and third spinal ganglia were increased to the size of a small bean (5x7 mm.), were of hard consistence, and protruded as tumor masses on the inner side of the dura. The same miliary tumor formation was present on the inner surface of the dura as far down as the middorsal area. The gross appearance of the brain when removed at autopsy, studded closely as it was with small tubercles, gave the impression at the first glace of a syphilitic meningitis. The more careful examination and the finding of the tumor masses in the other viscera led to a correct diagnosis. The microscopical examination presented a typical picture of carcinoma. The involvement of the cortex was unquestionably an extension from the meninges, and was more a displacement of the cortex, and could, in no sense, be considered a true infiltration. The spinal ganglia involvement in this case is a rare lesion and the authors have been unable to find a recorded case in which this condition has been definitely stated. The involvement of the cranial nerves is explained by the presence of miliary carcinomata in the piaarachnoid, surrounding their points of exit. There were no tumor masses on the nerves themselves.

Journal of the American Medical Association, February 1, 1908.

Cleft Palate.—G. V. I. Brown cites the advantages of the operative relief of cleft palate; the relief from a distressing deformity, the more healthful conditions of the nose and pharynx thus made possible, the possibility of gradual permanent speech improvement throughout life and of some degree of immediate change for the better from the operation. No person with cleft palate need be utterly discouraged; however bad his condition, in nearly every case and at almost any age, operation is advisable. In one of Brown's most satisfactory cases the patient was fifty years old at the time of operation. No unnecessarily

forcible methods should be employed in early infancy, and bad results of early operation, which are frequent causes of slow speech, may be much benefited by corrective operations. The correction of deformities of the dental arch is also a matter of importance. He attributes considerable importance to heredity, not necessarily of obvious palate defect but often of some peculiarity of speech which seems to have been transmitted to the offspring in an exaggerated form and with manifest anatomical deformity. The avoidance of specially technical and complicated methods of speech training is also a point emphasized by him. He has seen better results from the simpler methods. The use of the voice in singing is mentioned as one of the easiest and most natural ways to overcome unfortunate speech habits.

The Antimicrobic Action of Bromine.—G. C. Kinnaman reports the results of experiments made in order to test the antimicrobic efficiency of bromine. The following organisms were employed: *Bacillus prodigiosus, B. anthracis* and spores, *B. tuberculosis, Staphylococcus pyogenes aureus, Streptococcus pyogenes, Blastomyces dermatidis, Actinomyces bovis.* The methods are given in detail. In order to approach as nearly as possible conditions in the tissues, solid media were employed exclusively and a large number of tubes were used. The results with each separate organism are given in tabulated form and analyzed and discussed. The final deductions are given substantially as follows: 1. In a solution of bromine we have a germicidal agent with a peculiar selective action for certain groups of microorganisms and that acts more or less indifferently toward another group. On cocci and fungi a 1 to 300 solution exerts a marked germicidal action, but on bacilli, especially spore-forming ones, its action is disappointing, a 1 per cent. solution having to act for a considerable period of time before causing death. 2. It differs from an ideal antiseptic in that (*a*) it is hard to prepare, being very irritating to the eyes and mucous membranes; (*b*) it is very unstable, having to be kept in a glass container, and even then it gradually loses its power and fresh solutions are required; (*c*) it is not markedly penetrating; (*d*) it has to act for a considerable time to be effective on all microorganisms; (*e*) it coagulates albumin. 3. It approaches an ideal antiseptic in that (*a*) it is nontoxic and nonirritating in effective strength; (*b*) it does not produce an appreciable stain. 4. Lastly, it is needful to state that in order to be effective on all classes of microorganisms a 1 per cent. solution must be used for the period of one hour.

Landry's Paralysis.—An interesting case of Landry's paralysis is reported by J. K. Mitchell, who considers that the disease is probably due to some toxin produced by organisms, as yet unidentified, in the blood and tissues, and possessing a selective action on the spinal cord. Other analogous conditions, multiple neuritis, migratory neuritis, and family periodic palsy, may be similarly explained. The resemblances of these to the condition in question are remarked and the history of the case is given in full. The case was a typical one: the paralysis of the patients involved all four extremities, was entirely motor, all the reflexes were absent, and there was a distinct reaction of degeneration in the anterior tibial and calf muscles of the right leg and a less marked one in the left anterior tibial muscles. It later appeared in all the leg and arm muscles except those of the left thigh. The breathing apparatus was very slightly involved, if at all. He improved under treatment with galvanism, hot and cold applications to the spine, and small doses of ergot, and was discharged, walking well, early in July, 1905, after a stay of eighty-two days in the hospital. His improvement continued through the summer, but he was reported as having a slight relapse, possibly hysterical, in October. This lasted less than a week, and he has been perfectly well ever since. The only antecendents mentioned that could be considered causative were exposure to cold and wet.

Nervousness.—J. Punton considers a large class of psychopathic neuroses on the borderland of insanity, the subjects of which, he thinks, are often a puzzling problem to the physician and the sociologist. They cannot be managed or classed with the ordinary insane, and are not properly taken account of in our social organization. From a study of 1,200 cases observed by him during the past six years, he includes this class of patients under five heads: 1. The adolescent, made up of young persons of both sexes, suffering primarily from the various neurotic complications of the developmental period, and including the incipient cases of dementia precox. 2. The emotional or phrenasthenic class, presenting every degree of emotional weakness, lack of will power, etc. The chief pathologic conditions represented are the so-called hysterias or phrenasthenias, the hypochondrias, and the morbid jealous and erotic states. 3. The exhausted or psychasthenic class, including the neurasthenics, incipient melancholiacs, paranoiacs and confusional cases following toxic infections, and the various sexual perversions. The chief clinical characteristics, however, are seen in all the degrees of exhaustion of the nervous system, the morbid self introspection, selfishness, suspicion, etc., and all degrees of morbid fear. 4. The prodigal or dissipating class, which includes the inebriates, the drug fiends, etc. 5. The impulsive or vicious class: the kleptomaniacs, pyromaniacs, etc., who come perhaps nearer to actual insanity than do the members of the other classes named. Still another might be added: the senile or decadent class. Members of all these classes fall within the borderlands of insanity and require special treatment adapted to their cases. Drugs and surgery fail here or serve only as adjuvants to moral treatment, healthful suggestion, together with judiciously used hygienic measures, massage, etc., and for these to have their best effect there should also be a change of environment, isolation, mild discipline or restraint, together with the removal of the causes of the condition whenever possible. Punton pleads for legal provisions for securing the needed restraint and isolation of these patients without their having to be committed as insane. This necessity, which now exists in most parts of the country, is not only a hardship to individuals but also to their families, and is a serious embarrassment to their proper treatment. Many of these patients absolutely refuse treatment or the measures needed for their welfare and there is no way to compel them. As a result they finally too often pass into a hopeless condition and recruit the ranks of the incurable insane.

Iodoformic Acid in Phthisis.—H. Stern describes his method of using iodoformic acid in chronic ulcerative phthisis. He employs two solutions: a 1 per cent. solution for hypodermic use (from 10 to 30 drops, beginning with smaller dose and gradually increasing to the higher dose, or even to 40 drops in some cases) and a weaker solution made from this (1 part in 150) for internal use. Of the latter, one tablespoonful representing 1 c.c. of the stronger solution is an average dose. Some stomachs will not bear this and it should then be given still further diluted. In other cases sometimes larger doses can be tolerated; the behavior of the stomach can be taken as a guide. The solution may be given from two to five times daily, after breakfast, but before the other meals. It should never be combined with other drugs, but should be taken at least an hour apart from any other medicine. The intramuscular injections are, however, the most rational method and the only one by which we can directly influence the phthisical process in the lungs, and he usually injects into the thickest portion of the interscapular muscles. Full directions are given as to details, antiseptic precautions, etc. Stern's theory is that the formic acid is the more effective or more important component, and that the action of the iodine is that of a catalyzer, and in many ways analogous to that of a ferment. The specific effects of iodine are never observed from the ingestion or the injections. The primary therapeutic effect seems to be a local one, relieving pain, lessening cough and expectoration and improving the character of the latter, and checking ulceration and caseation. Constitutionally it appears to affect assimilation in a rather direct way and the patient begins to gain in weight before any appreciable local changes have been produced. The accessory treatment with drugs, diet, fresh air, etc., is described, the yolk cure in particular.

The Lancet, January 25, 1908.

Fenestration of the Anterior Faucial Pillars.—P. Watson Williams describes and figures the throat of a boy of 18 years without any symptoms whatever. He considers the case one of congenital defect on account of (1) absence of any cicatrices or unevenness in the margins of the fenestra; (2) bilateral symmetry of the malformation; (3) arrangement of the strands of mucous membrane and the muscular fibers and that they obviously corresponded to the anterior faucial pillars, and (4) the fact that although the posterior faucial pillars did not show fenestration, yet the palatopharyngeus muscles were collected into a separate bundle of fibers on each side, with only a thin layer of mucous membrane in continuity with the lateral walls of the pharynx.

The Effect of Exercise on the Opsonic Index of Patients Suffering from Pulmonary Tuberculosis.—From careful observations made by A. C. Inman, it would appear that the opsonic index has shown that the exercise has supplied the stimulus needed to induce artificial autoinoculation, and that its systematic graduation has regulated this in point of time and amount. This cooperation with the natural efforts of the blood has enabled Dr. Latersen to

send his patients back to their accustomed work, however hard it may be. But the investigation has done more than explain a successful mode of treatment. Dr. Paterson states that with the aid of the opsonic index he can regulate the stimulus with scientific accuracy and obtain his results more certainly and more rapidly. This, of course, involves work in the laboratory. But it also means a more rapid and more certain discharge of the patient, which is the main object of the sanatorium, and as a consequence of this the power to meet a larger number of patients. An elaborate system of charts is included in the paper, presenting results in a graphic form. Exercise must be most carefully graduated and the temperature chart be most carefully watched, work being at once stopped when fever appears.

Graduated Labor in Pulmonary Tuberculosis.—M. S. Paterson details the methods pursued at the Brompton Hospital Sanitarium. The points so far determined appear to be as follows: (1) Suitably selected patients can be gradually trained to do the hardest navvy work for six hours a day, the result being that their general condition is much improved whilst some lose both their sputum and their tubercle bacilli. (2) Certain patients who do not improve on light work show marked improvement on harder work. 3. Patients who have slightly overexerted themselves and are kept at rest for the few following days are subsequently not only not worse, but may be in their own opinion better. Observations so far lead to the conclusion that graduated labor is a definite medical treatment for cases of pulmonary tuberculosis and raises the general health and resisting power of the patients. Finally, the author strongly expresses the opinion that the combination of rest, pure air, and overfeeding is not the only treatment for chronic pulmonary tuberculosis, and equally strongly advises those physicians who may adopt these suggestions contained in this paper to pay particular heed to the word *graduated* and to remember the importance of the temperature of 99° F.

British Medical Journal, January 18 *and* 25, 1908.

Some Physiological Aspects of Gastroenterostomy.—H. C. Cameron presents the following conclusions: 1. On a purely milk diet, in non-malignant cases, after gastrojejunostomy there is a slight but definite diminution in the power of digesting and absorbing fat. 2. On a mixed diet, rich in fat, for the most part in the form of butter, this diminution in power disappears. 3. On a milk diet and on a mixed diet, rich in fat, the results are the same, whether there is obstruction at the pylorus or not. It is therefore improbable that the diminution in power of digesting milk depends upon whether the duodenum is or is not short-circuited out of the alimentary canal. The cause must be common to both obstructed and non-obstructed cases, and is probably to be found in the regurgitation of alkaline bile and pancreatic juice into the stomach and in the consequent reduction of gastric acidity, together with the inhibition of the rennin. 4. That in cases of recurrent intractable duodenal or gastric ulceration, an operation is indicated which will ensure the complete loss of the acid reaction of the stomach, while the benefit at present conferred in ulceration by gastroenterostomy is due to the partial loss of that reaction. That such an operation would consist in closing the proximal end of the bowel and implanting the distal directly into the stomach. That where gastroenterostomy is performed the opening should be near the cardiac end of the stomach, and that the anastomosis should be simple, not Y-shaped, nor with enteroenterostomy. 5. That the complete digestion of fats on a mixed diet is due to the specific stimulating effect on the pancreas of a hormone produced by the fats themselves. 6. A case of malignant pyloric obstruction, after partial gastrectomy and posterior gastrojejunostomy, showed complete power of dealing with fats.

The Conveyance of Whooping-cough from Man to Animals by Direct Experiment.—H. A. Macewen reports the following experiment: A full-grown and in every way healthy cat was placed in confinement in a building far removed from the wards in which whooping-cough patients were isolated. Sputum and vomited material were then collected from selected cases of typical whooping-cough without bronchopneumonia or other complications. These substances were mixed with milk and administered to the cat, which took to the new diet with a fair degree of relish. For seven days this emulsion of sputum, vomited material, and milk formed the animal's sole source of nutriment. At the end of that time it was put upon ordinary milk once more. After about fourteen to seventeen days, it was noted that the cat was getting into a languid condition; it lay at the back of its cage, and took little note of what went on around it. It had little appetite; when milk was placed before it, it would lap a little without any of the zest which characterized its attitude towards food at the commencement of its confinement. About a month after the beginning of the experiment it was noted that the animal had a choky cough, which was always followed by vomiting. Some time later it developed a spasmodic cough, accompanied by a well-marked whoop, which even persons unacquainted with the nature of the experiment at once pronounced to be whooping-cough. When these spasms came on, the animal, rising and clinging to the bottom of the cage with its claws, coughed and whooped in a manner which left no doubt as to the nature of its complaint. The conclusions to be drawn from the above experiment would seem to be: (1) That whooping-cough is beyond doubt an infectious disease. (2) That the specific virus is contained in the sputum or vomited material or both. (3) That infection may take place either during the process of swallowing or by ingestion of the infective agent. (4) That cats are susceptible to whooping-cough and may therefore occasionally be the means of disseminating the disease.

Hypersensitiveness to Antidiphtheritic Serum.—R. T. Thorne has had occasion to inject himself on several occasions with the serum and finds that he is peculiarly sensitive to its effects. These generally assume the form of urticarial rashes and general malaise. On the last occasion, seven days later his suboccipital glands were large and tender and his malaise was so great that he felt compelled to stop work. A few hours after retiring, he awoke feeling sick and vomited until quite exhausted. The rash was by this time quite general and in some places on the abdomen raised fully half an inch. At 3 P.M. the next day he was again seized with vomiting, which lasted quite half an hour. By this time his tongue had swollen, due to the urticaria, and he found some difficulty in breathing. At 4 P.M. the joints below the hip and shoulder were attacked, and became so swollen that he could not bend his fingers. By 8 A.M. the rash had almost gone, and he felt better, but on getting out of bed found that he could not stand, and fainted. By the evening he felt well, but very shaken and weak. Temperature was normal during the week preceding the attack. Nothing had been eaten which could have upset him, and he believes that the vomiting was due to urticaria of the stomach. He also experienced some thoracic and abdominal pain during the height of the attack. Injections of the same serum practised by him on several patients gave no such unpleasant results. The cure is of further interest in that it presented progressive increase of reaction to serum with more than two injections at long intervals.

Formaldehyde in Alopecia Areata.—J. J. McInerny records the case of a young girl with a circular patch 3 inches in diameter on the scalp at the side of the occiput, hairless, smooth, and shining. The treatment consisted in painting it with a 20 per cent. solution of formaldehyde. This was done every day for the first week or two, until signs of inflammatory reaction appeared. The treatment was then suspended, and a sedative ointment applied. When the inflammation subsided the formaldehyde was again continued, stopping the application as soon as inflammatory trouble appeared. This routine of treatment was persevered in for about six or nine months. About this time a growth of hair made its appearance, continued to grow, and in every way corresponded with the surrounding hair. One year after cessation of treatment the growth of hair was continuing in a perfectly normal way.

Status Lymphaticus in Relation to General Anesthesia.—W. J. McCardie gives a general summary of our knowledge on this subject dating back to Plater's original observation in 1614 that the thymus was enlarged in certain cases of sudden death. According to Kundrat, these cases are characterized by the presence of a thymus of greater or less size, by an enlarged spleen with varying degrees of prominence of its follicles, by tumescence and hypertrophy of lymphatic glands in various regions (especially of the mesenteric, retroperitoneal, and cervical), by noticeable prominence and multiplication of follicles at the base of the tongue and in the pharynx, by enlargement of the tonsils and swelling of solitary follicles and Peyer's patches in the intestine, by a dilated heart (especially is the right ventricle dilated), and extremely flaccid cardiac muscle. In addition, there is sometimes found a small heart, contraction of the aorta, and dark fluid blood in the heart cavities. To Kundrat's pathological complex may be added less constant features—namely, great pallor of the skin, enlargement of the tongue, enlargement of the thyroid gland, infantilism, edema of the lungs and brain, fatty changes in the liver, and alterations in the bone marrow. As Kundrat remarks, similar more or less definitely characterized cases making the hypothesis of a lymphatic constitution probable are found scattered through the statistics of chloroform deaths. The author has examined the rec-

ords in thirty cases of status lymphaticus deaths and finds that chloroform was used in 17, ether in 6, and C. E. in 5. Two were doubtful cases and the anesthetic was nitrous oxide. Two S. L. deaths have been recorded under local anesthesia. It is most important to diagnosticate the lymphatic status before operation. We may gain some information by examining the upper air tract, for it has been noted that in some of the S. L. cases the lymphatic follicles in the pharynx, sinus pyriformis, and on the anterior surface of the epiglottis, as well as on the pharyngeal walls, have been much enlarged. In one case the follicles in the vault of the pharynx formed lobular soft rolls sprinkled with white dots formed by the numerous follicles. In many cases, probably, these enlarged follicles have been overlooked. In most cases also the tongue follicles have been enlarged. The author regards enlargement of the tongue, which he believes has not hitherto been mentioned in the literature on the subject, as an important aid to diagnosis. Enlargement of the organ was noted by him post mortem in 2 of the 5 fatal cases he has recorded. Another important matter concerns the relation of enlarged tonsils and adenoids to this diathesis. These lesions have been noticed in practically every fatal case. The author states that he does not look on enlarged tonsils and adenoid growths as merely local manifestations, but as indicating a marked tendency to general lymphatic enlargement; and, more than this, he believes that if patients in whom these lesions were present could be examined post mortem there would be a very large proportion of them in whom much more evidence of lymphatism would be found. Adenoids and tonsils do not stand by themselves, but are associated with a lymphatic condition elsewhere. Hochsinger examined three children with adenoids radiographically and found in all of them an enlarged thymus.

A Fatal Case of Status Lymphaticus.—The patient of H. Hilliard was a very nervous man of 21 years, slim, with a weak heart, and a great cigarette smoker. Operation for circumcision was done at noon, the patient having breakfasted at 8 A.M. and smoked cigarettes all the morning. Nitrous oxide and ether were used and the operation begun while the patient was lightly under the anesthetic. Just as the prepuce was severed the patient turned ashy and stopped breathing. Under artificial respiration, nitrite of amyl inhalations, and rhythmic tongue traction, he was quickly restored. Operation proceeded, but a second attack came on, in which the patient died. Autopsy revealed the thyroid gland was enlarged, and with degenerative changes. The thymus gland was persistent, and weighed 24 grams; it extended downwards towards the pericardium. The heart was dilated, with thin, flabby walls, showing on microscopic examination considerable fatty degeneration of the muscle fibers. The spleen was greatly enlarged, and there was a supernumerary spleen; both showed on section very great overgrowth of the follicles and connective tissue. In the intestines the Peyer's patches and solitary follicles were excessively developed. The mesenteric glands were all enlarged.

Berliner klinische Wochenschrift, January 6, 13, and 20, 1908.

An Unusual Case of Stone Cough.—Bickel and Grunmach report this remarkable case in which the patient, a woman of thirty-five years, coughed up at intervals concretions of considerable size, which apparently were formed in the large bronchi. Seven years before she had suffered with pleurisy and erysipelas. Since this time the cough had persisted, with occasional periods of remission. In 1902 and 1906 she had several hemoptyses. The paroxysms of cough occur suddenly, are very severe, and, with or without other sputum, sandy particles or concretions of varying size are brought up singly or several at a time. Such attacks occur two to three times a year. The first one was six years ago. Examination of the chest showed evidences of a tuberculous process, although the sputum contained no tubercle bacilli. Examination with the Roentgen rays showed the presence of numerous large areas of calcification. The chemical analysis of the concretions, of which more than three dozen had been preserved by the patient, ranging in size from that of the head of a large pin to that of a pea, showed that they contained lime, mucin, bronchial epithelium, crystals, and leucocytes.

The Value of Wassermann's Syphilis Reaction in Surgical Diagnosis.—Karewski describes twenty-eight cases in which the method of fixation of the complement was resorted to as a test for the presence of syphilitic infection, ten of the number proving negative and eighteen positive. The results of the tests accord so well with the clinical diagnosis that the author speaks very favorably of the value of the measure as a deciding criterion in doubtful cases, though its complicated nature renders it unsuitable for routine use. A negative serum reaction of itself is not decisive, but from the differential standpoint may be of value in making it probable that suspected lesions are of nonsyphilitic origin. A positive result affords the quickest and most reliable proof of the presence of the disease. It is therefore especially valuable to the surgeon, since it gives him a definite basis for action in cases in which all other signs are absent, and under these circumstances it should never be omitted. If the history or the evidences of previous lesions establish the diagnosis it is unnecessary to resort to this test, since it throws no new light on the character or activity of the manifestations under observation.

Specific Precipitin Formation on the Injection of Human Feces.—Fuerstenberg was able to produce the formation of specific precipitins in rabbits by treating them with extract of human feces. For this purpose the material was triturated with about five times the amount of physiological salt solution, the mixture allowed to stand over night and then centrifuged for fifteen minutes. The supernatant fluid was filtered several times through paper and in one series of observations was heated for half an hour to 58 degrees in order to kill most of the intestinal organisms. In another series the fluid after filtration through paper was filtered through a porcelain filter. In a third series the extract was concentrated by exsiccation over calcium chloride to about a third of its volume. These preparations were injected into the animals subcutaneously or intravenously. The intravenous injections, particularly of the porcelain filtered fluid, were best borne. Eight injections of 2 to 3 cm. were given intravenously at intervals of about a week. The serum of these animals had then acquired a specific precipitin which reacted only to extracts of human feces and not to those of rabbit or sheep dung. Monkey dung was not tested.

Tuberculin in Renal Tuberculosis.—Pielicke considers that the tuberculin treatment of tuberculosis of the kidney has its indications, and describes a case which was arrested if not cured by this means. He concludes that in dealing with isolated tuberculosis of the kidney tuberculin sometimes appears to effect a cure. When the disease is bilateral and is complicated with pulmonary tuberculosis the tuberculin treatment is indicated. The question of whether a kidney is to be extirpated or tuberculin is to be used must be decided from case to case; if the condition is advanced and is unilateral extirpation will certainly prove the best treatment. If, after a nephrectomy, it is found that the second kidney is tuberculous, the tuberculin treatment is to be recommended. Tuberculin also appears to yield particularly good results in cases of tuberculosis of the bladder.

French and Italian Journals.

Neurasthenia from the Point of View of Pathogenesis and Clinical Manifestations.—Dr. Renzi says that the name neurasthenia corresponds to a proteiform affection having diverse etiological elements and associated with other affections. It is not simply a condition characterized by fatigue, loss of tone, and exhaustion, but there are other symptoms due to an increase of energy and functional disturbances. In neurasthenics the cardiovascular pressure, muscular force, and memory are preserved and are even better than in a normal condition. Neurasthenia is the disease of modern life and due to cerebral fatigue. It is most variable in its clinical syndrome and may vary from an insignificant manifestation to the gravest psychosis. By its generalization in modern times and the psychical nature of the affection it deserves to be called the new psychosis.—*La Riforma Medica*, December 7, 1907.

Primary Malignant Tumors of the Ovary.—P. J. Dreyfus tells us that cancer of the ovary occurs once out of every ten affections of the ovary that require laparotomy. There are two periods of maximum appearance, puberty and the menopause. It is not very rare in children, and those moreover who have genital malformations are subject especially to its appearance. It is very frequently bilateral, a condition which may be accounted for by transference of cancer cells from one side to the other. The important symptoms are amenorrhea, pain, tumor, and ascites. Histologically we may distinguish epithelioma, sarcoma, and endothelioma. Epithelomata may arise from the epithelium of simple or dermoid cysts, germinative epithelium, follicular epithelium, and Wolffian epithelium. The sarcomata are polymorphous. They may originate from a fibroma, ovarian stroma, theca externa of a follicle, or a corpus luteum. Endotheliomata arise at the expense of lymphatic endothelium and blood-vessel endothelium. There is no other treatment for this kind of growth than removal early and complete. It is always advisable to remove the uterus and all the adnexa.—*Archives Générales de Chirurgie*, October and November, 1907.

Book Reviews.

The Medical and Surgical Knowledge of William Shakspere. With Explanatory Notes. By John W. Wainwright, M.D., New York: Published by the Author, 1907.

One of the greatest of English essayists—the late Walter Bagehot—has left us a most illuminating paper on, to use his own title, "Shakespeare—the Man," in which he argues with the hot lucidity typical of his style that, contrary to the commonplace assertion, we *do* know a great deal of the real Shakespeare. He says among other things that "to a great experience one thing is essential—an experiencing nature;" and to those sceptics who think an author's character cannot be deduced from his works he says that presumably "people do not keep a tame steam-engine to write their books." In the volume before us the writer has, by his own road, come round to this identical point, and made it clear to his readers by a most abundant and interesting array of quotations from the whole field of Shakespeare's work, that if he had not actually studied medicine (and there is no evidence that he did beyond this one of deduction from his works) his mind was yet a storehouse of the medical knowledge of his day. In the scholarly preface to this delightful little book the author points out that the same may be said of his knowledge of theology, or law, or astronomy, and sums up in words that cannot be bettered: "It is reasonably certain that he was accustomed to associate with all classes of men and women; that he was a keen observer, had an exceptionally retentive memory, sought knowledge from whatever source, could intuitively grasp a thought and put it to immediate use, mentally finish what was only begun by others. All people with whom he came in contact contributed to his knowledge, unconsciously, perhaps, more often than otherwise. He learned from all stations of life, from the Court to the gutter."

The extracts are grouped under the several headings of Medicine, Surgery, Mental and Nervous Diseases, Obstetrics and Midwifery, Therapeutics, Pharmacy, and Toxicology, Anatomy, Physiology, Hygiene and Dietetics, Ethics, and Medical Jurisprudence. Many of the quotations are striking, but not the least interesting feature of the brochure will be found in the running commentary following the quotations themselves. The frontispiece is an excellent photogravure from a photograph of the portrait which was the original of the Droeshout engraving in the first folio edition edited by Heming and Condell.

The Conquest of Cancer; A Plan of Campaign. Being an Account of the Principles and Practice Hitherto of the Treatment of Malignant Growths by Specific or Cancrotoxic Ferments. By C. W. Saleeby, M.D., F.R.S. (Edin.), Author of "Worry," "Heredity," "Evolution," "Psychology," "Sociology," "Ethics," etc. New York: Frederick A. Stokes Company, 1907.

The title of this work, it is needless to say, is intended to be prophetic rather than historical, for even Dr. Saleeby, enthusiastic as he is, and somewhat "previous," has modified his earlier statement, founded, we believe, on the result of one experiment in a mouse, that the cure of cancer has been found. His position now is that the nature of cancer has been discovered and that it is only a step further to fix upon a definite cure. We fear the step will have to be taken in seven-league boots, notwithstanding the undoubted fact that cancer has in a few cases apparently been cured by injections of trypsin. The book is a popular presentation of Dr. Beard's seductive theory, expounded by him so interestingly in the Medical Record, of the personality of cancer—a warring "lævoman" inclosed in the tissues of the normal or "dextroman"—and of the destructive action of the pancreatic ferments upon this unwelcome twin. The book bears evidence of having been hurriedly written, dogmatizes unwarrantably on uncertain and debatable points, and is lamentably wanting in the scientific calm which becomes a writer on as yet unproved theories. If it were addressed to professional readers these faults, while calculated to create an unfortunate prejudice against the subject, would not matter so much, but the lay reader, to whom the appeal is made, has not the technical knowledge or the training necessary for a judicial weighing of the evidence presented. The day of secrecy in medical science is past, but the time for presenting theories as facts and thereby arousing hopes which may prove to be vain in the minds of sufferers from mental disease has not come, and we hope, for the sake of these sufferers, that it will never come. The excuse which the author gives, or implies, for appealing directly to the laity is that the professional channels of publicity have been closed to him and to Dr. Beard. We do not know how far this charge is justified in England, but it is certainly not so in this country. The medical journals in the United States have freely opened their columns to the author of the theory and to other writers who have reported cases of cancer treated with trypsin, and we venture to say they will always be open to anyone who has theories or facts to present contributing to a solution of the problem of cancer or of any other of the diseases of mankind. The medical journal is the place for such presentations and discussions, but not the secular magazine or a book addressed to the laity.

Dr. Saleeby's book, however, despite its faults and its injudicious appeal to the laity, is worthy of consideration by the medical reader. It states Dr. Beard's theory in fairly readable fashion, and those who have not seen the originals can get a very good idea of the subject from this paraphrase and elaboration of Dr. Beard's articles. The author endeavors, though strugglingly and not always successfully, to treat of his subject judicially, and he admits that there are therapeutic problems not yet worked out, though he has no doubt that the solution will be reached in time. Doubtless it will in one way or another, but we fear Dr. Saleeby's premature appeals to the laity will not further the cause of which he has constituted himself the champion.

A Textbook of the Practice of Medicine. For Students and Practitioners. By James Magoffin French, A.M., M.D., Formerly Lecturer on the Theory and Practice of Medicine, Medical College of Ohio. Third Revised Edition. 135 Illustrations, 25 Being Full-Page Plates in Tints and Colors. New York: William Wood & Co., 1907.

The third edition of this excellent work on practice appears greatly enlarged, and whereas the first edition was stated to be chiefly for the use of students, the present work appeals to the practitioner as well and takes its rank with any of the other standard treatises on internal medicine. The general arrangement of the subjects remains the same, however, and, despite the amplification, the very clear and simple descriptions retained from the earlier editions preserve the character of the work as one especially adapted to the needs of the student as well as to those of the practitioner. Parts I and III, which are particularly serviceable to the student, dealing with general pathology and clinical methods of examination, have been retained substantially as before, except for the necessary revision and slight enlargement, the most extensive alterations being in the sections on practical medicine. Special attention has been devoted to tropical diseases, and the chapter on animal parasites made more complete and more modern, a new classification and nomenclature having been adopted in place of those which have descended through successive generations of medical textbooks. The sections on treatment are particularly good, the author being a moderate optimist, seeing the possibility of the arrest and cure of many diseases, yet not being carried away by an unreasoning belief in specifics. To the young practitioner especially French's practice may be safely recommended as one of the best of the modern textbooks, a sound instructor in pathology, and a trustworthy guide in therapeutics.

Nouveau Traité de Chirurgie, publié en fascicules sous la direction de A. Le Dentu, professeur à la Faculté de Médecine de Paris, et P. Delbet, professeur agrégé à la Faculté de Médecine de Paris. 33 fascicules grand in-8, avec figures.

I.—Les Grands Processus Morbides. Par P. Delbet, Chevassu, Schwartz et Veau. Paris: J. B. Baillière et Fils, 1907.

This is the first volume of the new edition of Le Dentu and Delbet's well known surgical treatise which represents for France what "Deutsche Chirurgie" is for Germany and Bryant and Buck's Surgery is for this country. The French work is not profusely illustrated, at least this first volume contains but 53 figures in the text and no plates. As the title of this first part indicates, it deals with the great morbid processes which are at the basis of most surgical conditions, in other words, with general surgical pathology—traumatisms, infections, vascular and tropic disturbances, and scars. The subjects receive a broad and all-sided treatment, though chiefly from the surgeon's viewpoint. The book is chiefly of value as a theoretical treatise on surgical pathology, but there are under each heading sections on diagnosis and treatment which add considerably to its practical usefulness. It is amusing to see Lord Lister's name printed "Listre" (on p. 21) in a Gallicized form. An excellent summary of the serum treatment of tetanus is included in the chapter on infections.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at St. Louis, Mo., December 30 and 31, 1907.

THE PRESIDENT, DR. CHAS. W. OVIATT OF OSHKOSH, WIS., IN THE CHAIR.

AFTER a brief address of welcome by Dr. JOHN YOUNG BROWN on behalf of the local profession, which was responded to by Dr. CHARLES E. BOWERS of Wichita, Kan., the reading of papers was begun.

The Largest Common Duct Stone on Record.—Dr. WILLARD BARTLETT of St. Louis, Mo., reported this case and exhibited the stone. The patient was a man, 46 years of age, with a history of gallstone disease extending over twenty years, which was plainly referable to the common duct. The stone in the duct could be palpated through the abdominal wall; still the man was jaundiced only at times. The stone measured four inches in length by one inch and a half in diameter, and weighed two and one-half ounces. The duct was partly sutured and drained for one month. Five months later the patient was in better shape than he had ever been in his life before.

The Pathological Gall-Bladder.—Dr. B. B. Davis of Omaha, Neb., in a paper with this title, said that because a patient had lived through an operation it did not necessarily mean that he was cured. Unless the gall-bladder continued to functionate normally and painlessly, the patient was not willing to consider himself cured. Many patients in whom drainage was instituted had a recurrence of the symptoms and a secondary cholecystectomy became necessary. This usually produced a relief of all symptoms. The following conditions in the writer's experience called for extirpation: (1) Adhesions between the gall-bladder and the stomach, colon, or omentum. (2) Stenosis, or even narrowing of the lumen of the cystic duct, due to old inflammation or pressure necrosis from an impacted stone. (3) Gall-bladders with thickened walls due to long-continued cholecystitis. (4) When external fistulæ or fistulæ between the gall-bladder and the stomach or colon were present. (5) When the gall bladder wall was made up of scar tissue largely displacing the normal muscular coats. (6) When the gall-bladder was found filled with mucus, clear or tarry, and there was no fresh bile. (7) In gangrene of the gall-bladder. (8) In perforation of the gall-bladder. (9) In empyema of the gall-bladder, the mucous membrane being usually destroyed over large areas. Cholecystostomy in the presence of the conditions given as a rule did not relieve, and extirpation had to be done later. In most cases the cholecystectomy could be done as a primary operation, without adding to the operative risk. The writer disclaimed taking too radical grounds, since he believed in the retention of every gall-bladder that would not be a menace to future comfort.

The Differential Diagnosis of Duodenal Ulcer from Gallstones.—Dr. W. D. HAINES of Cincinnati, O., said that prominent symptoms in common were pain, vomiting, and flatulence, together with the deleterious influence which these symptomatic manifestations exerted on the general health of the patient. Both complaints were referred to the upper right quadrant of the abdomen, and while the pain in cholelithiasis, which was sharp, decisive and of sudden onset, was referred to a point opposite the right ninth costal cartilage, it might radiate over the entire right side of the abdomen, and not infrequently found expression in the right shoulder joint. Again, the pain might be most intense in the region of the tenth dorsal vertebra. Vomiting, if present, was characteristic in that the ejected matter was bile-stained, consisting largely of mucus, and afforded no relief to the patient. Hot fomentations might give temporary relief, but full doses of morphine were usually required to allay the terrible suffering. In duodenal ulcer the pain recurred at intervals, was less sudden of onset and severe in character. It was described as a burning or gnawing sensation, which might last a few days or continue for months after the primary attack. Unlike the lancinating pains of gallstones, pain in this disease was markedly influenced by the presence or absence of food in the stomach. A certain degree of relief invariably followed the ingestion of a full meal, lavage of the stomach, or the drinking of a quantity of alkaline fluid. The spasm of the pylorus was a frequent accompaniment of ulcer, but wholly unknown in early gallstone cases. Spasm of the diaphragm was evidence of severe pain, which, if referred to the region under consideration, indicated gallstones, as ulcer pain, in the absence of perforation, was not of sufficient severity to produce this symptom. Gaseous distention spoke for ulcer, and the accompanying pain quickly subsided after expulsion by eructations or vomiting. Muscular rigidity and local tenderness were present in both ulcer and stone cases. Pain in duodenal ulcer was due to the passage of acri-acid stomach contents and to distention by gas. Vomiting was of less value as a symptom than either pain or distention, but it was well to remember that vomiting was full and free, followed by marked relief, and ceased promptly in ulcer cases, leaving little depression and no nausea. In late or recurrent gallstone histories, vomiting was a prominent feature, and the same might be said of chronic ulcer. The slight transitory disturbance of the one and the invalid-dealing influence of the other would materially assist in putting one right in the diagnosis. Hemorrhage occurring during an attack of gallstones was accidental, but it was prominent as one of the late manifestations in ulcer. Jaundice, like hemorrhage, was a late symptom and might be present in either of the conditions under consideration. Jaundice following lancinating pain of sudden onset, localized in the upper right quadrant of the abdomen, radiating over the right chest wall or accompanied by pain in the right shoulder, would warrant a conclusion of the presence of gallstones. Constipation was one of the early effects of duodenal ulcer. In a certain percentage of the chronic and some of the acute cases of stone and ulcer, differentiation would be reserved for that erstwhile, much-used, sometimes abused, method of diagnosis—exploratory incision

Peptic Ulcer of the Jejunum.—Dr. F. GREGORY CONNELL of Oshkosh, Wis., reported one case of this character, in which a secondary gastroenterostomy was performed three years after anterior gastroenterostomy for pyloric ulcer with stenosis. After a consideration of the subject and an analysis of thirty-nine cases, he concluded as follows: (1) Peptic ulcer of the jejunum was a possible result of gastrojejunostomy. (2) It was probably of more frequent occurrence than the 30 reported cases indicated. (3) It followed the long loop operation more often than the no loop operation. (4) The symptoms might be latent until either acute hemorrhage or perforation occurred. (5) The symptoms might be chronic and simulate those of gastric or duodenal ulcer. (6) Peptic ulcer of the jejunum should be considered in all cases of return of symptoms after gastrojejunostomy. (7) A symptomless period after the operation was necessary to eliminate a continuation of the condition for which the gastrojejunostomy was performed. (8) A differential diagnosis could rarely be made before operation. (9) Prophylactic treatment, aiming to reduce the excess of acidity, should be instituted after all gastrojejunostomies for benign conditions, and should be continued for at least six months. (10) Treatment would be either medical or surgical, similar to that for gastric or duodenal ulcer. (11) The possible occurrence of ulcer of the jejunum was

an additional reason for performing gastrojejunostomy only where it was positively indicated, namely, by pyloric obstruction.

Acquired Atresia of the Common Duct Due to a Gall-stone.—Dr. John C. Hancock of Dubuque, Ia., after referring to the literature, reported the case of a woman, aged 66, who gave this history in connection with her illness, which had existed two years and nine months: Family history was negative. Previous history also negative, except for severe headaches and occasional palpitation. Her present illness began October, 1901, with sudden and severe pain in the abdomen in the region of the ninth and tenth ribs, vomiting, purging, chill, and fever. The attack lasted from one to two days, and subsequent prostration delayed the patient's return to her home for two weeks. Three weeks after her return home she began to experience excruciating soreness in the same region as before, and extending around the ribs to the right shoulder blade and shoulder. This condition, with variations in severity, lasted all winter. April, 1903, patient experienced a sensation of pushing and grinding, starting in the right side. This extended across the back and abdomen, and lasted two weeks. With this girdle pain the patient was confined to bed and jaundice set in. This had persisted. From a weight of 116 pounds patient gradually lost 36 pounds, but the loss of strength was not as great in proportion as the loss in weight. With the jaundice there was loss of appetite, itching, dullness of the sensorium, many slight chills, and once a severe attack with high fever. The stools, which had been dark, became clay colored. Urine had been scanty and high-colored most of the time since jaundice set in, and the patient had to micturate as often as four times a night. April, 1904, her feet began to swell slightly and later the body. The bowels, irregular and costive before, began to be irregular and loose, moving three to four times in twenty-four hours, and accompanied by pain in the lower abdomen. At present the patient suffered no longer with headaches, but faint at times, had enjoyed fair appetite until the last few days, was not troubled with belching or heartburn, had some shortness of breath, but no cough, occasional palpitation, which, however, antedated the illness in question. Stools watery and cream-colored. Examination revealed a short, jaundiced woman, with spare body above the waist, prominent abdomen, and slightly edematous lower extremities; pulse 90; temperature 99.2°; respiration 16; sclera bile-tinged; lungs negative; heart apex beat third interspace inside the nipple, and no murmurs. Liver dullness extended from the fifth rib in the mamillary line to four fingers' breadth below the costal margin. Ascites was present and prevented the examination of other abdominal viscera. No tumor was made out, nor tenderness, except near the costal margin on a line between the ninth rib and umbilicus. The circumference of the abdomen at the umbilicus was 96 centimeters; urine high-colored, acid, sp. gr. 1,032; bile present; albumin, slightest possible trace; no sugar; occasional hyaline casts; some small round epithelial cells, probably from the kidney; a few abnormal red blood corpuscles, abundance of various forms of large epithelial cells, probably from the bladder and pus corpuscles. The next day six quarts of ascitic fluid were removed, having a specific gravity of 1,011, and a trace of albumin. The abdomen was now soft and permitted satisfactory palpation. The liver was felt to be hard and smooth for three fingers' breadth below the costal margin on the right, and to reach more than half way to the umbilicus, thence across the epigastrium transversely, where the edge could be easily grasped between fingers and thumb of the same hand. In the epigastrium, slightly to the right of the median line below the liver margin, numerous hard nodular masses, slightly tender and movable, were made out. The liver itself was not tender, but the region of the gall-bladder was still markedly so. Spleen was enlarged. The abdomen otherwise was negative. After carefully considering the hazards of operation in the presence of jaundice, and more particularly ascites, the patient decided upon operation. Accordingly, through a vertical incision through the right rectus the abdomen was opened. The residual ascitic fluid was removed. Viscera were found congested, and in addition in the upper right quadrant densely adherent. So far hemorrhage was not extraordinary, but upon separating the adhesions the fresh surfaces bled freely and continuously, in spite of ligatures and the fact that no demonstrable vessels were severed. A hard, cirrhotic liver and several enlarged lymphatic glands were readily found, and a small contracted gall-bladder identified. From this stage on further exploration had to be done almost entirely by palpation on account of hemorrhage. A movable stone, the size of an olive, was felt in the common duct, but no evidence of malignant growth was made out. By this time the hemorrhage had become alarming and had so obscured the field that the attempt to incise the common duct to allow for bile drainage had to be abandoned. The field was packed and the abdominal wound partly closed. Patient left the table showing signs of shock and hemorrhage and died fourteen hours later from complete exsanguination, in spite of calcium chloride, etc. Shortly after death a partial autopsy was made. The abdominal cavity was found entirely free from clots, although the pelvis contained free blood. The findings at operation were confirmed. The gall-bladder was contracted to the size of an olive. The common and hepatic ducts were greatly enlarged. At the junction of the cystic and common ducts was found a cicatricial contraction of cystic duct. In bladder and duct were several small flat concretions. Upon removal of the large stone from the lower end of the common duct the condition of atresia of this duct was discovered. The lower end of the duct was perfectly smooth, without a sign of opening into the duodenum, and might be likened to the blind finger end of a rubber glove. The bile tract, a portion of the liver, the duodenum and pancreas were removed *en masse* and examined both macroscopically and microscopically. Macroscopically the liver presented the appearance of hypertrophic cirrhosis, but under the microscope the changes of atrophic cirrhosis were present. Macroscopic examination showed atresia of both the common duct and that of Wirsung. The duct of Santorini could not be found, and there was entire absence of the papilla on the duodenal side. Microscopically the ductus choledochus, that of Wirsung, the pancreas, and duodenum showed chronic inflammatory changes, but no malignant elements. Bile was present in the common duct. The stone was found to be a mulberry calculus, composed almost entirely of cholesterin, with the poles made up, superficially at least, of bile pigment and calcareous salts.

Dr. Charles H. Mayo of Rochester, Minn., said that he and his brother had done twenty-two hundred operations on the gall-bladder and ducts. Of this number there were over six hundred cholecystectomies and about three hundred operations on the common duct. A few years ago they had a leaning towards the removal of the gall-bladder if there was any disease of the mucosa perceptible, while now they were inclined to leave the gall-bladder if the cystic duct was open. The operation, however, of the removal of the gall-bladder as a secondary operation was not as serious as operations on the common duct which might be necessitated later, after the removal of the gall-bladder. They believed that the removal of the gall-bladder resulted later in a majority of cases in the distention of the common duct. They have had five cases of the reformation of stones in the common duct, and three of them after the removal of the gall-bladder. In all of the series he only recalled two cases in which, after the primary operation of removing gallstones from the gall-bladder, stones reformed in that viscus.

Dr. C. H. Wallace of St. Joseph, Mo., reported the

case of a woman upon whom he operated some two years ago for the removal of stones in the gall-bladder. The gall-bladder itself was found in a fairly good condition; the mucosa was not diseased, not very much enlarged, and the walls not much thickened. A number of stones were removed, and drainage established. Some two or five weeks ago this woman began to have attacks again. In the third or second attack she passed three or four small gall-stones. This was a case in which the question arose as to whether in doing a second operation the gall-bladder should be removed or drainage again tried. He thought surgeons got the impression from those who did a large amount of gall-bladder surgery that if in a given case there was a healthy gall-bladder, with stones in it, where the mucous membrane was not diseased, if the stones were removed and the gall-bladder drained, the patient could be assured that he or she, as the case might be, would get well. Occasionally, however, such patients returned, and the guarantee of such a prognosis cannot be given now with as much assurance as in former years.

Dr. J. E. Summers of Omaha, Neb., said that seven or eight years ago he reported a case in which there was a tight stricture at the lower end of the common duct, and also of the cystic duct, the common duct acting as a reservoir. The liver was very much hypertrophied, as was also the spleen. The technique employed was to open the common duct and to make an anastomosis between this and the duodenum. The patient made a nice recovery after a long time. Mayo Robson had also reported one or two of these cases, which Dr. Hancock did not mention in the literature of the subject, and he thought Dr. Wm J. Mayo had reported one or two others.

Dr. James E. Moore of Minneapolis said that within the past six months he had seen two cases of gallstones of great interest. One was the case of Dr. Mayo, and the other a case of his own. Both cases had practically the same symptoms. In his case there were, first, the ordinary gallstone symptoms. The patient was operated on, the stones removed, and the gall-bladder drained. Later the patient had a recurrence of symptoms, and at the operation gallstones were found in the gall-bladder; the gall-bladder was found diseased, and cholecystectomy was performed. The interesting feature about his case and that of Dr. Mayo is that these women are at the present time suffering again from gallstone colic. What should be done? The only hope was that there was a stone or stones in the common duct that might be reached. He had not yet operated upon a case of that kind. He thought, however, it was quite possible that these stones might be in the hepatic duct, because in the case on which he operated and removed the gall-bladder the stones were many, small, and soft, looked like millet seeds, and evidently came down from the gall-bladder at the time. He had the feeling that this woman would surely have trouble some time in the future. It was only two years since he did the cholecystectomy, and now she was having serious symptoms and very grave attacks, but without jaundice.

Dr. John C. Morfit of St. Louis, Mo., reported two cases of bowel obstruction due to gallstones, which had occurred within sixty days of each other in the last year. A woman of 80 had acute obstruction of the bowel, with finally total obstruction when he saw her. The bowel was obstructed at about 18 inches above the ileocecal valve by a stone an inch and a quarter in diameter, and an inch and a half long, which evidently came from the gall-bladder. She made a very satisfactory immediate operative recovery. Pneumonia, however, developed on the eleventh day and she died on the fifteenth day after operation. A post-mortem examination was not made, but the question arose as to the pathological anatomy in the region of the gall bladder. How did this stone get into the intestine? Did it come through the common duct, or did an inflammatory anastomosis occur between the gall-bladder and some portion of the alimentary canal? He believed that there was, as a result of pre-existing inflammation, an ulceration or anastomosis between the gall-bladder and duodenum or possibly some portion of the small intestine. Within a few weeks thereafter another woman, 56 years of age, presented herself with exactly the same condition. He was able to strike a stone in practically the same situation at once, the stone being of the same size and same consistency. The intestine was opened by a linear incision, the stone liberated, the incision closed, and the patient made an uneventful recovery.

The Use of Harrington's Solution in the Treatment of Suppurative Inflammations of the Knee Joint.—Dr. J. E. Summers of Omaha, Neb., said that it had been proven experimentally and clinically that Harrington's solution would kill all of the common germs met with in surgical practice in from twenty seconds up to one minute, and was not caustic. After thorough washing of the hands in hot soapsuds and then immersing them for two minutes in this solution, if cultures were taken, there should be an entire absence of germs. Even when there was no preliminary washing of the hands before their immersion in the solution for two minutes, the results were remarkable. The author reported an interesting case in which this solution was used, and said that while his experience with Harrington's solution was not great, it could be used very advantageously in infective wounds where it was applicable. After thorough surgical cleansing of a wound or abscess cavity, the solution was allowed to remain in contact with all its surfaces for from three to five minutes; it was then irrigated or sponged away, and the particular wound dressed as required. Anyone who would try Harrington's solution would like it. It had, besides, its established antiseptic property, the power, when applied to a raw surface, to produce a copious discharge of serum, thus aiding the washing away of noxious elements from the wound.

Dr. Charles H. Mayo emphasized the value of Harrington's solution as an antiseptic, and said that it was one of the best and least destructive in use for suppurating wounds.

The Removal of Gallstones in the Common Duct Through the Lesser Omentum.—Dr. M. L. Harris of Chicago said that the gall-bladder and its contained stones might be enucleated without much difficulty, but should the common duct harbor stones it might be impossible to reach them by the usual route. He did not now refer to those cases in which a stone was lodged in the ampulla of Vater, and which could be reached by the transduodenal route, but to those in which the stone was in the upper part of the duct or movable within the duct, and which, owing to the pyloric end of the stomach having been drawn to the right by the adhesions, lay behind this portion of the stomach as well as the duodenum. In two cases of this kind which came under his care, after a somewhat prolonged fruitless effort to reach the common duct in the usual way, he succeeded in reaching and removing the stones by following a new route through the gastrohepatic or lesser omentum above the pyloric end of the stomach. These two cases he reported in detail. The advantages of this route in these cases were the great saving of time over attempting to work one's way through an almost impossible mass of adhesions, and the lessened dangers of injuring the duodenum or other structure.

Removal of the Whole or a Part of the Humerus.—Dr. E. M. Sala of Rock Island, Ill., said the removal of the whole or a part of the humerus was a comparatively safe operation, and one which should be carefully thought of in all cases where amputations were formerly the first aid to the injured in serious disturbances of the humerus. He thought too many arms had been sacrificed in the past that might have been saved had the surgeon cared to try

an extirpation of only the diseased portion of bone. Almost any kind of an arm was better than no arm. Before the days of aseptic surgery there possibly was some excuse for amputating anything in the shape of an arm that looked bad, but to-day, with the aid of aseptic and antiseptic methods, we were expected to attempt greater feats in surgery. That it was possible for a whole or a part of the humerus to be extirpated, and the patient given a useful arm and forearm, was beyond doubt. One-third of the upper end of the humerus might be removed and the patient appear as though nothing had ever happened to the upper extremity, except shortening on that side. The whole humerus might be removed without serious disturbance to the hand and wrist, especially if care was exercised in saving the muscle-spiral nerve in its separation from the bone. Dr. Sala reported the cases of two patients, operated on some thirteen years ago, in which the results of conservative surgery were remarkable.

Dr. Roland Hill of St. Louis, to show what can be accomplished by conservatism in the treatment of lesions of the humerus, said that about two weeks ago he presented a case before the St. Louis Medical Society, in which the upper part of the humerus was involved, and which was removed. This man had been taken ill in 1892, with a septic condition involving the upper part of the humerus and also the glenoid part of the scapula. In the winter of 1905 he came to the city and Dr. Morfit opened the joint, removed some dead bone from the upper part of the humerus, and also from the scapula. The patient returned home at the end of five weeks in a much better condition, but in the summer he began to be septic again. He came to the speaker in July, at which time there was a constant discharge of pus. He opened up the parts freely, removed the head of the bone, cleaned out the cavity and packed it. The patient improved very much, went home, but the joint did not heal up. There was a constant discharge, and in March, 1906, the patient came back with the idea of having the arm removed. Dr. Hill made one more effort to save it, opened it up, curetted the diseased tissue, and found there was some necrosis at the head of the bone extending down to the medullary cavity, which was removed. He thoroughly dried it and sterilized the parts with carbolic acid and alcohol, and then filled the cavity with Moorhof's bone mass. The arm was not dressed again for a week. In about six weeks thereafter healing had taken place. The arm was kept in a sling for four months, at the end of which time the patient was able to use it, and had been using it ever since.

Dr. W. D. Haines of Cincinnati mentioned a case in which he removed almost the entire humerus from a boy, ten years of age, in 1898, who had a number of sinuses along the outer surface of the arm. No attempt was made to save the periosteum; the entire bone was removed down to within two inches of the condyles. The patient has to-day a useful arm. He endorsed this method with reference to primary amputation, and said that amputation, if really necessary, could be done later.

The Surgical Treatment of Hallux Valgus, with Bunion.—Dr. Charles H. Mayo of Rochester, Minn., recommended for this condition a curved incision, base down, over the metatarso-phalangeal joint. The bursa of the bunion was preserved, and left attached to the base of the first phalanx. The head of the metatarsal bone with the greater part of the bunion was removed. The bursa was turned into the joint in front of the cut end of the bone. Thus was utilized a ready formed bursa to prevent joint fixation, a result which was obtained in other joints with difficulty by turning fatty tissue into a joint to develop such bursa. The general function of the joint was nearly perfect and continued to be so after many years.

Early Restoration of Function After Excision of the Elbow in Tuberculous Cases.—Dr. G. G. Cottam of Rock Rapids, Iowa, related the history of the case of a young farm laborer who suffered from tuberculosis of the capitulum humeri, with ankylosis of the elbow, in which it was very desirable to secure early use of the arm. Excision by Kocher's incision was used, and through this means and by radical modification of the after-treatment from that usually employed, together with the fact that the operation was done before the soft parts were extensively involved, brought about the desired result, the patient being able to do the heavy work of his occupation after the eighth week. The paper concluded with the following summary of the points involved in producing such an outcome: (1) Early operation, that is, as soon as it was certain that the disease was present and not yielding to conservative treatment. (2) Choice of a method of operating which preserved the integrity of all the important nerves and muscles. (3) Removal of sufficient bone to insure free mobility. (4) Immobilization in the extended position, with maintenance of the angle of deflection. (5) Active motion at the end of three weeks.

Anesthesia Fatalities in Iowa.—Dr. L. W. Littig of Iowa City, Iowa, sent a circular letter to 3,500 physicians practising in Iowa. Eight hundred replies were received, many of them containing information which led to reports of fatalities by men who did not reply to his first letter. He had rejected reported chloroform fatalities occurring from two to four days after anesthesia, because he did not think it was possible to secure anything like reliable data in this class of cases. He had rejected ether fatalities occurring at the close of a long and difficult operation. He had excluded cases in which he thought that the operation itself was of sufficient magnitude to cause death on the operating table, or soon thereafter. He had excluded obstetric fatalities in which placenta previa or severe hemorrhage complicated delivery. He had excluded cases in which pneumonia or other lung complications followed gall-bladder or other abdominal work. The report contained 63 chloroform fatalities. Of these 63 fatalities 10 occurred in dental practice. One fatality was due to choking during anesthesia. There were 5 fatalities in confinement in which chloroform was used, and in which the reporter blamed the chloroform. There was one confinement fatality, in which ether was used and in which the reporter blamed the ether. There was one hyoscine-morphine, ether, chloroform sequence, and one chloroform ether sequence. There was one late chloroform fatality, with jaundice. The author concluded that (1) chloroform was vastly more dangerous than ether, and especially so in minor work, and at the beginning of administration. The chloroform ether sequence was especially bad. (2) In the class of work mentioned, chloroform was so much more dangerous than ether that its use should be most emphatically condemned, and that "the surgeon (quoting H. C. Wood, writing sixteen years ago or earlier) is not justified in using chloroform except under certain circumstances and for very definite reasons." (3) Chloroform was especially dangerous in dental work and should not be used. (4) Chloroform was not free from danger in obstetric practice.

The Abdominal Incision.—Dr. Clifford U. Collins of Peoria, Ill., read a paper on this subject, in which he drew the following conclusions: (1) Abdominal incisions should be placed so they will pass through both oponeurosis and muscle. (2) The incision in the aponeurosis and the split in the muscle should run in different directions. This could be done in a large majority of abdominal operations. (3) A longitudinal incision should not be made through the linea alba or the sheaths of the rectus at a right angle to the combined pull of the three side muscles when it was possible to avoid it. (4) For very large tumors in cases where the character and location of the pathology was in doubt, the longitudinal incision was probably necessary. (5) If the longitudinal incision was necessary the split in the rectus should not be continuous

with the aponeurotic incision, but should be placed to one side, and preferably through its inner half to avoid the intercostal nerves which entered the outer half. (6) It would take longer time and more experience to demonstrate the correctness of these conclusions.

Arthrodesis and Tendon Transference in Paralytic Club-Foot.—Dr. John Prentiss Lord of Omaha, Neb., advised arthrodesis and tendon transference in cases of paralytic club-feet for the following reasons: (1) To prevent the return of the deformity, which so often occurred where braces alone were used. (2) To avoid loss of time during which the child became confirmed in the habit of deformity. (3) Because younger children learned to walk anew much easier than did those of more advanced years. (4) Where the patient was financially unable to meet the expense of prolonged treatment with braces. (5) By preventing return of deformity, the parents did not fall into the habit of thinking nothing could be done. (6) It utilized to best advantage the remaining muscular power and gave the best possible results to be obtained in these cases. The degree of work done depended upon the amount of deformity. Ordinarily, removal of the articular surfaces from the tibio-astragaloid, astragalo-scaphoid, and calcaneo-cuboid was done to effect arthrodesis. In addition, transference of the tibialis anticus to the common extensor for toe-drop was done, while in extreme equino-varus astragalectomy with removal of the joint surfaces from the calcaneo-cuboid articulation, and even suturing the tibialis anticus to the periosteum on the outer side of the cuboid, might be demanded. In some cases, even the flexor longus hallucis was brought through the inter-osseous membrane and sutured to the common extensors. In the rare cases requiring muscle-splitting, he said we should avoid severing the transverse nerve fibers in the body of the muscle. Dr. Lord had used catgut sutures, except where the tension was heavy, when he used fine silk, boiled in bichloride, dried and reboiled in paraffin, before operation. In more than 40 consecutive cases the results had been very satisfactory. In joint cases cigarette drainage was used to take away oozing. This was gradually removed, no suppuration taking place. Heavy casts were applied as long as six months, the use of the foot being gradually increased after three or four months. The results had been very gratifying, the majority of patients having been able to discard braces or crutches within a reasonable time.

President's Address.—Dr. Oviatt did not deal with any concrete surgical problem, but his address consisted of a few thoughts bearing on the practice of surgery that naturally came to one who had spent the most active years of his life in the work. No attempt was made to take up the history further than to show that previous to the year 1800 but few discoveries were made that marked any distinct advance. The evolution of surgery in the past century had kept pace with the development of science along other lines, wonderful as this had been. With the perfected technique of antisepsis and asepsis, it seemed that the acme of surgical science had been reached; but in the light of discoveries it would be rash to attempt to place a limit to the future of surgery. The ambitious medical student did not usually get far into his college work before he decided to become a surgeon. This decision was brought about largely through what he saw in surgical clinics and from his observation of the position held by the surgical leaders of the profession. Young men who elected to become surgeons should make sure that they possessed the special aptitude and then be willing to devote a long period to preparation for the work. Attention was called to the fact that there was much that passed under the name of surgery being done by incompetent and ill-trained men. Some of it was honest and well-intended, but much was for purely commercial ends. A spirit of graft had pervaded the profession that was undermining morals and ethics. A partial explanation for the existence of this condition was found in the fact that this was an age of commercialism. We were known to the world as a nation of dollar chasers. This, and the overcrowding of the profession with men from inferior schools, were in large part responsible for fee-splitting and the commission evil. The existence of this class of medical colleges was less excusable when it was considered that the better schools ranked with the best in the world, and that they were ample to afford instruction for all who should enter the profession. Enough well-prepared men of character were entering the field to insure the upholding of the lofty ideals that had characterized the profession in the past. We might, therefore, take a hopeful view of the future. Another aid in the elimination of the graft evil was coming from the people themselves. The public mind was especially active at this time in combating graft in all forms. The moral standards set for professional men and men in public life were going to be higher in the future, and with the limelight of public opinion turned upon the medical and surgical grafter, the evil would cease to exist. Hand in hand with this reform, it was hoped that an established standard of qualification would be established for those who assumed to do surgery.

The Significance of Abdominal Tenderness in Locating Lesions of Viscera.—Dr. T. C. Witherspoon of Butte, Montana, referred to the physiology of the sensory nerves of the abdominal viscera, and discussed at length the effect of lesions of the viscera in the production of pain. The somatic areas of pain referred from the viscera and their significance in diagnosis were pointed out and expatiated upon; likewise the character of visceral pain. He spoke of disturbance of the sensory function of the somatic nerves, with coincident disturbance of visceral function. Lastly, he called attention to those pains of central origin which were referred to the abdomen. Pott's disease, tabes, and tumors in the spinal canal illustrated this class. Usually the subjective pain was not accompanied by tenderness, at least not of any acuteness.

Etiology of Epithelioma.—Dr. Arthur E. Hertzler of Kansas City, Mo., began with the hypothesis that the limitation of epithelial cell development was set by the chemical difference in the basement membrane and epithelial cells. Experiments proved that those chemicals which unite (stain) connective tissue *in vivo* caused an atypical epithelial cell proliferation resembling closely a beginning epithelioma. The development of atypical cells was limited because the action of the chemical upon the connective tissue was limited. This resulted in constancy for stains having these characteristics. It was negative for connective tissue stains which did not stain *in vivo*, or for nuclear stains. Areas in which atypical cell proliferation had been brought about by such means the fibers, after fixation, did not stain with the ordinary fibrous tissue stains, while the fibrous tissue in regions not so treated stained in the characteristic manner. Applying facts so deduced clinically, the general statement was ventured that epitheliomas occurred in those regions where alkaline secretions were permitted to come in contact with the fibrous tissue by irritation, thus producing the resistance of the connective tissue to the invasion of epithelial cells or to some change primarily in the connective tissue, *e.g.* prolonged exposure to leucocytes, as in chronic inflammation, or to some overstimulation of the epithelial cells. Either of these conditions would lead to a disturbance of chemical balance and permit the invasion of the epithelium.

Preparatory and Postoperative Treatment.—Dr. James E. Moore of Minneapolis said that as a rule preparatory and post-operative treatment, aside from the sterilization of the operative field and the dressing of the wound, had more to do with the comfort of the patient than with his recovery, for emergency cases very commonly did well, and surgeons frequently performed suc-

cessful operations away from home and left the after-treatment to a physician little skilled in the care of surgical cases. In all but exceptional cases, where some organ, the bladder, for example, had to be prepared for operative procedures, prolonged preparatory treatment was unnecessary and inadvisable. It was not in keeping with modern surgery that surgeons should operate their patients off the street, but it was sufficient to have the average patient enter the hospital on the day preceding the operation. In weak patients and where a very severe operation was to be performed, a hypodermic of 1-30 grain of strychnine just before operation was helpful. The operative field should be shaved, thoroughly disinfected, and a sterile dressing applied the evening before the operation. Every operating room should have an experienced anesthetist, because it added to the patient's comfort and safety, and allowed the surgeon to give his undivided attention to the operation. He pointed out the many things pertaining to the operation itself which had a decided bearing on the after-treatment. The patient always thought the stitches and bandages were too tight, and it was very important that the surgeon should know that they were not so. Most stitch abscesses were caused by tight sutures, and tight bandages were the cause of untold suffering. Thirst was the greatest source of suffering after operation, and in the management of this symptom many mistakes were made. His patients all got water after operation, and they convalesced much more comfortably than those who were deprived of it. All surgeons agreed that the patient was better without food for a time after operation, for he did not suffer from hunger, and an effort to force feeding would surely disturb his stomach. Aside from opiates and mild cathartics, medicine had very little place in post-operative treatment. His patients got it only to meet definite indications. Attention should be given to the relief of pain after operation. The proper care of the bowels after an operation had much to do with the patient's comfort. In every case the question naturally arose, When shall the patient get out of bed? All were agreed that old people should get up at the very earliest period possible for reasons well understood, but there was still a great diversity of opinion as to when a younger patient should get up. Every abdominal operation was of sufficient importance to justify the patient in remaining in bed for from one to three weeks, owing to circumstances, and he was usually content to do so. There was no crying need for getting the patient out of bed the day after an abdominal operation. He was safer and more comfortable in bed for a few days at least. He recently operated upon a colleague for chronic appendicitis, who made the statement that he intended to get out of bed the day after operation; that staying in bed for a week after such a simple operation was all nonsense, to all of which the speaker readily acceded with a mental reservation. On the first day the patient quietly curled up on his side, and Dr. Moore smiled without comment. On the second day he was still in bed, and when he asked him why he was not up, he mildly suggested that he go to a warmer climate, and very emphatically stated that his viewpoint had changed.

The Appendix as a Femoral Hernia Content.—Dr. Charles S. James of Centerville, Iowa, reviewed the literature, after which he reported the case of a female, aged 77 years, who for four days had noticed a painful lump in the right groin. The patient was in usual health previously, but had noticed a small lump at this point for several years. Symptoms were negative, except that the pulse was 96 and temperature 102°. The abdomen was not distended. There was nothing noted indicating intraabdominal lesion. There was a prominent brawny swelling, three and one-half to four inches in diameter, indurated and semi-fluctuant, presenting the characteristic appearance of a suppurative gland over Poupart's ligament. There was no impulse. A diagnosis was made of a local suppurative process, with probable femoral hernia. Operation was performed at the Centerville Hospital one hour later under spinal anesthesia. The abscess cavity was dissected up with difficulty and found to extend through the femoral hernia opening as far as the appendix. A separate abdominal incision disclosed an incarcerated loop of ileum, gangrenous, and two perforations. He resected five inches of the intestine, and resorted to end-to-end anastomosis with suture. The appendix was ligated, severed, and removed with the closure of the stump in the usual manner. Both incisions were closed with continuous catgut suture. The time of the operation was one hour and a quarter. The patient was conscious, but suffered no pain throughout the operation. Convalescence was pleasant, and recovery excellent. He presented photographs and specimen.

The Association or Confusion of Appendicitis with Other diseases in the Female Pelvis.—Dr. A. E. Benjamin of Minneapolis said that any inflammatory disease within the abdomen primarily involving one organ might from continuity or contiguity result in other tissues or organs being involved. The blood supply of the abdomen and pelvis was such that infectious microrganisms might be carried from one diseased organ to another, thereby starting a similar disease in a part through which this infected blood flowed. The lymphatics might also convey disease to organs in the line of their distribution. The nerve supply of the organs of the lower abdomen and pelvis and their sympathetic relationship was such that pain might be referred to localities not affected. It was possible for more than one form of disease to exist within an abdomen simultaneously, and the symptoms to become quite complex thereby. Besides actual disease, there might exist a misplaced position of one or more organs, thereby changing the symptoms considerably in the presence of disease, or resulting in contiguous organs being affected because of this displacement. Also the misplaced position alone might cause distress, which resembled some actual form of disease. The character of the disease, the variety of each form of disease, the number of organs involved, the associated displacement of organs, the temperament, environment, and avocation of the individual sufferer were all factors to be considered in summing up the case. A careful personal history, a thorough physical examination of the individual, with the aid of chemical, bacteriological investigation, and a searching examination with all the apparatus at command, *i.e.* cystoscope, proctoscope, microscope, and *x*-ray, would clear up the majority of cases. In certain cases if no positive diagnosis could be made, there might be clear indications for operative interference to cure the disease. In complicated cases a thorough search through a proper-sized opening should be made to terminate the symptoms complained of, and a record of all findings for future reference made.

Torsion of the Omentum.—Dr. W. W. Grant of Denver, Colo., reported an interesting case of torsion of the omentum, and said that in view of the most common association of this diseased condition with hernia, it became a matter of unusual interest in this particular case as to its possible connection with hernia in earliest childhood. He was positive, from the nature and character of the adhesion, the condition of the intestine and absence of any indication of disease, past or present, of every other organ or part, that it was of long standing. It seemed possible that it could have dated from the existence of hernia in childhood without causing intestinal obstruction or torsion at an earlier date. The vomiting might have been due to a momentary obstruction from volvulus due to the adhesion and intestinal peristalsis. In the intra-abdominal cases the symptoms closely resembled those of acute appendicitis. The tenderness and dullness at an

early period covered a wider area than in appendicitis; yet, if on the right side, both subjective and objective symptoms simulated those of acute appendicitis. If hernia existed, one should especially be on guard as to the differential diagnosis.

(To be continued.)

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held November 6, 1907.

DR. ADOLF MEYER, PRESIDENT, IN THE CHAIR.

Preliminary Report on the Significance of the Ocular Signs and Symptoms of Dementia Præcox as Observed in a Series of 115 Consecutive Cases.—Drs. H. H. TYSON and L. PIERCE CLARK presented this communication. The cases were from private practice, clinics, and the metropolitan asylums. Definite changes were invariably found. The fundus changes as seen clinically were divided into three stages, in the order of their occurrence. First stage, congestion of the discs, hyperemia, and edema, dilated veins, contracted arteries, and blurring of the edges of the discs, of varying degrees, constituting a low grade perineuritis of the optic nerve; second stage, congestion of the nasal side with temporal pallor of discs, dilated veins, and contracted arteries; third stage, pallor of discs, dilated veins, and contracted arteries, constituting partial or complete atrophy of the optic nerve. All forms of dementia præcox were under study. The more rapidly deteriorating forms showed the most marked changes. The cases embraced both users of alcohol and tobacco, and abstainers. Theoretically, the changes are probably due to a vascular toxin from liver or intestinal autoinfective origin. A vascular alteration with edema took place, resulting in disturbances of nutrition and slow degeneration of the nerve fibers. Cases in the first stage had shown fundus improvement under the usual treatment for intestinal autoinfection. Other eye symptoms found uniformly were: Enlarged pupils, negative sensory reflex, negative psychic reflex, negative Piltz reflex, diminished corneal sensibility, and concentrically contracted visual fields. No other psychosis presents similar conditions. The findings should be found useful in differential diagnosis, to a certain extent in prognosis, and possibly in the study of the pathogenesis and pathology of dementia præcox. Cases illustrative of the three stages were demonstrated to those members who used the ophthalmoscope.

Dr. C. E. ATWOOD had followed the investigations of Drs. Clark and Tyson, having seen nearly all the cases examined by them, and now looked for the changes in the optic disc and the other eye symptoms in every case of dementia præcox which came under his observation. In no case so far had he found the symptom-complex wanting. Recently, at the suggestion of Dr. Clark, he had been studying cases of infection, *e.g.* lead poisoning, quinine poisoning, and cases of typhoid fever, pneumonia, etc., in the hope of finding some similar changes in these conditions which might be of similar origin. In five men with typhoid infection averaging about twenty-six days' duration, four of whom smoked and drank, all showed haziness of the disc with some blurring of the edges and fullness of the veins. In one (the non-drinker and non-smoker) there was limitation of the fields to about 30°. In one only (of six weeks' duration) there was an appearance of central fullness (edema?), the cup not showing. In four women with typhoid fever averaging twenty-six days' duration, the discs in two cases were normal and in the other two anemic, the vessels being less full and the surface pale. In three men with pneumonia, all of whom smoked and drank moderately, the fundus in one was normal, and in the other two there was haziness of the edges of the disc with fullness of the veins, but no edema. In two post-operative septic cases, one a gangrenous appendicitis, the other an intestinal perforation, both exhibited haziness and venous enlargement but no edema. Both of these patients used alcohol and tobacco. A man with partial amblyopia from quinine poisoning who neither drank nor smoked, showed haziness, congestion, and edema of the nasal side, with fullness of the veins and pallor on the temporal side. Central scotoma was also present. The last case reported was one of infection from lead. A man, aged forty-four, born in Germany, drank beer, had slight arteriosclerosis, and had the occupation of making white lead in a factory. For seven months he had had double wrist-drop, and been under treatment in a neighboring town for this and lead colic, etc. Both discs exhibited central edema, pallor, and enlarged veins. The fields were contracted to 15° for red, 10° for green. There was central scotoma principally for red. V. = 20/30. The examination of seriously ill patients, *e.g.* with typhoid fever, etc., at Roosevelt Hospital, was facilitated through the kindness of Professor James, and made possible by the use of the electric ophthalmoscope.

Dr. WILLIAM MABON read the report of the findings in examinations of the fundi of twenty-five patients with dementia præcox and twenty-five with manic-depressive insanity at the Manhattan State Hospital. These examinations had been made by Dr. Holden, whose report was as follows: "Blin has reported in a series of observations of dementia præcox patients, a persistent congestion of the optic disc in 10 per cent, a persistent anemia in 8 per cent., and an alternating congestion and anemia in 6 per cent, with intermittent congestion or anemia in 45 per cent. more. However, I wish to say that the color of the optic disc varies within wide physiological limits and many of us do not like to speak of congestion or anemia of the disc unless the condition is pronounced and palpably abnormal. In none of these one hundred eyes examined did I find a congestion or an anemia that seemed to me significantly abnormal. The color of the disc may be said to depend largely upon the personal equation of the examiner. In the twenty-five patients with dementia præcox, the outlines of the discs were blurred more than in the average normal eye in eleven patients. In six of these eleven the large veins of the disc and retina were appreciably dilated. In the twenty-five patients with manic-depressive insanity, on the contrary, there was a blurred outline of the discs in but four patients and in but two of these were the large veins appreciably dilated. This blurring of the outline of the discs is in many cases of dementia præcox too pronounced to be considered physiological and must be regarded as pathological. It is due to cloudiness of the nerve-fiber layer of the retina and optic nerve, which in some cases seems to be caused by a cloudy swelling of the nerve fibers which can be individually made out, and in other cases perhaps to an edema of this layer without swelling of the fibers, or in other cases perhaps to both of these causes combined. In half of the cases in which the outline of the discs was blurred the veins of the retina were, as compared with the arteries, abnormally dilated. The condition may be analogous to the circulatory changes and edema found in other parts of the body in dementia præcox. In some cases it is so pronounced as to give rise to a characteristic picture, and from the examination of these twenty-five patients and of about an equal number previously examined, of which complete statistics were not kept, I should judge that the condition was to be found in about half the cases of dementia præcox and rather exceptionally, and in a less pronounced degree, in manic-depressive insanity." In view of Dr. Holden's statement that the condition was to be found in about half of the cases of dementia præcox

and exceptionally in manic-depressive insanity, it would seem advisable to make further investigations before reaching the conclusion that these conditions are of diagnostic significance.

Dr. P. C. Knapp of Boston called attention to the importance in these cases of refraction errors. In a considerable number of cases of brain disease, especially in cases of headache, he had found such a congestion of the optic disc as had been described, with blurring of its outline so great as to suggest beginning neuritis, but due, as further investigation showed, to a considerable degree of hypermetropia. It would be well to eliminate the possibility of refraction error before assuming changes in the optic disc. Dementia præcox was not the only mental disease, as suggested by Dr. Tyson, in which these changes were noted. They occurred in general paralysis in a number of cases, although they were less frequently seen than conditions of optic atrophy. He had seen a number of cases in which there was congestion of the disc and haziness of outline in which the changes were indubitably those of low-grade neuritis.

Dr. Adolf Meyer remarked that in order to prove that we are dealing with an inflammation and subsequent atrophy of the optic nerve, it would be very desirable to have sufficiently strong evidence of functional disorders of vision. In the absence of visual defect in cases of remission, etc., it remains to be shown that the appearance of the disc is not merely an incidental phenomenon of a general vasomotor difficulty.

Dr. Clark, in closing the discussion, said that in a number of cases at the Vanderbilt Clinic followed independently by Dr. Holden and by Dr. Tyson and himself, the results tallied exactly so far as the disc changes were concerned. In the report just presented Dr. Holden seemed to take it for granted that the only changes were congestion and haziness, whereas these formed only a part of a series of changes. These changes would not be noted unless the entire series were followed. Careful analyses in other types of mental disease had failed to reveal changes which could be confounded with those described. The different phases of the changes described, ranging from the congestive stage to the terminal one of general diffused atrophy of perineuritis, should be borne in mind, otherwise it was impossible to arrive at statistics. Of course there were optic changes in paresis, but this was not often to be differentiated from dementia præcox. He had made it a point to look for the physiological cupping of the disc, and if this could not be noted, to look for other features that go with dementia præcox. One hundred and fifteen cases, the number studied, would not establish any of these changes for diagnostic purposes. The work, as stated, was but a preliminary communication and must be verified by more exhaustive studies by many different observers before this eye syndrome could be finally considered as definitely established. The significance of these clinical features was tentative, and might undergo modification, but after two and a half years of investigation he was convinced that there was a characteristic toxic change going on in dementia præcox which must be recognized as a feature of the disease, possibly rendering it a somatic disorder with a mental accompaniment.

Dr. Tyson, in closing, said, with reference to errors of refraction, that it was only in high degrees that congestion of the disc was found, and that high hypermetropia was found in only one per cent. In atrophy it was only by contraction of the field and diminution of visual acuity, with cupping and pallor of the discs and contracted arteries, that the diagnosis was made; and finally in using the ocular signs and symptoms to aid in making a diagnosis, the entire eye symptom-complex should be used and not only the appearance of the fundus oculi.

The Anxiety Psychoses.—Dr. George H. Kirby read this paper. The effect of anxiety was of wide occurrence and appeared in a variety of psychoses, yet our clinical experience taught that there was a group of cases in which the anxiety appeared to stand out more or less as a fundamental symptom and not in association with additional features that would stamp the disorder as belonging with any other well recognized symptom-complex. These anxious depressions occurred mainly in the climacteric period or later in life, yet similar symptom pictures occasionally developed in earlier years. Kraepelin's recent proposal to merge the anxious depression into the manic-depression group as "mixed forms" was argued against by the author, who showed that Kraepelin was led to this change of position chiefly because he found that nearly all of the surviving cases of involution depression had terminated in recovery even after a prolonged course. This generalization exemplified to what an extreme degree the Kraepelinian statistical method might be pushed. The author's material afforded many reasons for keeping the anxious depressions apart from the manic-depressive psychoses—they appeared to arise out of a different etiology, showed important symptomatological differences, ran a different course from the manic-depressive cases, and were especially dangerous to the life of the patient. Various factors were mentioned which seemed to prepare the ground for the origin of the anxious effect, *e.g.* intoxications, organic insufficiency, advanced age, etc., and attention was drawn particularly to the great frequency with which the anxious mood arose out of prolonged worries and chronic emotional strains of various kinds. Cases were reported to demonstrate the importance of these psychogenetic elements in the development of the psychoses with anxiety. The cases studied fell into several groups, each of which seemed to have some prognostic significance. (1) Cases showing a simple form of anxiety or general uneasiness, apprehensive anticipations with or without ideas of sin. (2) A severer form showing anxiety with fear, perplexity, and allopsychic concepts. (3) Cases presenting the sensory-somatic complex, hypochondriacal trends, and feelings of unreality. (4) Cases developing with arteriosclerosis. The anxious depressions here described were not regarded as a special form of disease, but were considered rather as a type of reaction of fairly characteristic form in the evolution of which a number of factors participated; the psychogenetic features appeared to be particularly important. There seems to be a difficulty in adjustment to a situation which would naturally put the patient into an anxious frame of mind. In a smaller group of cases the physical causes seemed to be most important, and arteriosclerosis was especially apt to be accompanied by an anxious depression.

Dr. William Mabon was of the opinion that the anxieties should be kept separate from the manic-depressive group.

Dr. August Hoch of Bloomingdale said that Dreyfus tried to show that melancholia was merely a phase of manic-depressive insanity. Kraepelin agreed with him, as he stated in the introduction which he wrote to Dreyfus's book. But to do Kraepelin justice we must remember that he specially mentioned the fact of the differences in duration in the two groups of cases. While Dreyfus had made a valuable contribution in having shown that what most of us, with Kraepelin, regarded as permanent mental dilapidation, was in reality a recoverable condition; there was little gained by merely identifying the two groups of cases. There was no doubt as to a certain relationship, but there was also no doubt as to the differences, and we would have to say that these cases of melancholia were manic-depressive conditions under special conditions with special features and with certain peculiarities in course. It seemed to the speaker that we might regard the development of the anxiety and

the unreality complex in depression, in other words, those features which characterized the involution melancholia, somewhat in the light of complications, very much as we regarded complications in other diseases. By this we emphasized on the one hand the relationship and on the other hand the differences. He, therefore, quite agreed with Dr. Kirby that it was more profitable to keep the two groups separate. He was also very glad that Dr. Kirby emphasized the psychogenetic factors in the development of these cases, and he was quite sure that the work of Dr. Meyer and of Dr. Kirby in this direction was of great value, as it called attention to many facts which were clear enough when one looked for them, but which had often been singularly disregarded.

Dr. A. R. Diefendorf of Middletown, Conn., was inclined to agree with Dr. Kirby in his contention for the maintenance of the anxiety psychoses. In his own experience the melancholia of involution was not as prevalent as he had formerly believed. There were cases developing in the involutional period which showed anxiety, but were also accompanied by considerable psychomotor retardation. These cases which tended to recur should not be confounded with the anxiety psychosis, as they rightfully belonged to the manic-depressive group. He had failed to note psychogenic factors in the origin of his cases as being particularly prominent. In view of the fact that there was often a long prodromal period during which the patient was introspective, symptoms of the disease might be mistaken for psychogenic factors; that is, the patients failed to exhibit anxiety over troubles that had long existed in their lives, until they showed the first signs of the disease. With reference to the group designated by Dr. Kirby as the arteriosclerotic group, he saw no reason why they should not be considered as cases of arteriosclerotic insanity.

Dr. Charles L. Dana said that in private practice one saw many of the anxiety psychoses, though not of so severe a type as those described by Dr. Kirby. The condition undoubtedly made a clean-cut clinical picture, and to recognize it as a distinct form of melancholia was helpful in the prognosis and in the treatment. At the same time, the more he saw of melancholia the more it seemed to him that the "anxiety complex" occurred not only in the individual period, but in early life. It was his experience that nearly one-half of the cases of involutional melancholia coming on after forty or fifty gave a history of one or two attacks of "neurasthenia" years before, these often being mild psychoneuroses calling for no special attention from the psychiatrist. With reference to the psychogenic factor, he believed that the patients who developed these involutional psychoses were generally men and women of rather inferior mental caliber or persons who had worked in an environment which was too strenuous for them, and which, consciously or unconsciously, pulled them down. He could not recall any really brilliant mind that had suffered from involutional insanity. The women belonged to the type of women who had been worriers all their lives, who had had "previsions" and constant anxiety over details, and who were not fitted to carry on easily the work they were appointed to do. Melancholia in all its phases was the same thing, but occurring in different individuals it produced the differences noted. The same definite lesion occurring in one individual would produce melancholia with anxiety, in another retardation and apathy, and in still another, in addition to anxiety, there might be self-accusation or hypochondria. The differences in the clinical picture were due to the original differences in the make-up of the individual. He would represent melancholia by the term X, which meant a definite unknown lesion of the psychical apparatus, some break in association paths, perhaps; the special characters of self-reproach, depression, anxiety, retardation, would depend on the physique and character of the individual patient.

Dr. Adolf Meyer pointed out how, after all, a new standpoint, such as that of Kraepelin, of dividing all mental diseases into non-dementing and dementing processes was apt to tend to become a sort of all-embracing system with very few subdivisions. The welcome awakening of interest in the outcome of the disease had finally been pushed to the position of a logical decision, which naturally must either fit or not fit; but such division of all mental disorders would ignore many other matters which had long been thought of and could not be neglected. The fact that the outcome issue had been neglected for such a long time was no reason for making it an all-embracing issue for all decisions. To argue merely about the outcome would again lead to a great deal of guessing, and from a didactic point of view it would be better to fix the attention upon what was seen in the patient at the time of examination. It would be a much better working principle to try to recognize the concrete difficulties under which the patient labored, to examine the factors which led up to these difficulties, and to estimate the balance of the forces of the individual to meet the situation. This, in practically all cases of manic-depressive insanity, would naturally lead to the recognition of a non-dementing disorder in harmony with Kraepelin's nosology. Dreyfus's claim that the anxiety depressions were mixed conditions of manic-depressive insanity was another overstretching of a fruitful principle. As soon as one constructed mixed conditions of manic-depressive insanity, practically everything, even normal mental activity, could be included in this category. We already heard that hysteria should be included in the depressive psychoses. With regard to the psychogenic nature of the process, he was inclined to consider Dr. Dana's remarks very well to the point. Dr. Diefendorf's exception to the issue might hold for some cases, but it was absolutely undeniable that there was a larger percentage of palpable causes for a depression than in the ordinary manic-depressive insanities. Many manic-depressive conditions in the involutional period began to show anxieties. As soon as manifestations of manic-depressive features were noted one had symptoms which were of prognostic value. But the fact remained that the pure anxiety states for etiological and practical reasons formed a group worth differentiation.

Dr. Kirby, in closing, referred to Dr. Gregory's suggestion that anxiety was largely a general symptom which occurred in a number of psychoses, and recalled the fact that he had emphasized this point in his paper. Anxiety was a prominent feature in a variety of disorders, associated, however, with additional symptoms sufficient to mark the psychosis as belonging with some one of the better known types. Thus the anxious alcoholic cases mentioned by Dr. Gregory usually presented distinctive features, particularly in their evolution. He would agree with Dr. Diefendorf's suggestion concerning the grouping of the arteriosclerotic cases, but in many agitated depressions the arteriosclerotic basis was apt to be underestimated or even overlooked for a considerable time, perhaps until some definite cerebral attack occurred. When the arteriosclerotic nature of the disorder was clear, the proper group would be, of course, the organic brain diseases. He could not subscribe to Dr. Dana's conception of melancholia as a general disorder or a single disease, no matter whether it belonged to the manic-depressive or involution type of depression. The two forms of reactions, certainly when they were pure, were symptomatically and prognostically different. Provision must be made for a small number of cases which seemed to show admixtures or appeared to be transitional forms. Many cases of manic-depressive insanity showed anxiety, but here it was usually found in a fairly characteristic setting. These patients had nearly always a feeling of insufficiency or showed clearly some difficulty of thought or constraint in activity which did not appear in the anxiety psychoses described.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

October 23-25, 1907.

PHYSIOLOGY.

1. Give the functions of the pneumogastric (tenth cranial) nerve.
2. Discuss blood pressure.
3. Discuss color vision.
4. Discuss the function of the kidneys.
5. Name the digestive principle or principles of the following secretions and the class or classes of foods each acts upon: Saliva, gastric juice, bile, pancreatic juice.
6. Describe metabolism.
7. What are the functions of the liver?

NEUROLOGY.

1. Briefly describe the organ of hearing.
2. Describe reflex action.
3. What are the functions of the cerebrum and of the cerebellum?

ANATOMY.

1. Give the exact location of the macula lutea or yellow spot of Sommering, in the eye.
2. Into what parts is the brain divided and of what are the convolutions of the cerebrum composed?
3. What bone commences to ossify before any other bone in the body?
4. Into what parts is the sternum divided, and how many pairs of muscles are attached to the sternum?
5. Give origin, insertion, nerve supply, and action of the subscapular muscle.
6. How are the pulmonary veins formed? Where do they terminate? What blood do they carry? Do they have valves?
7. How is the circulation carried on after the application of a ligature to the brachial artery in the upper third of the arm?
8. Name the ductless glands.
9. Name the ligaments of the hip joint.
10. What separates the tonsil from the internal carotid artery?

PRACTICE OF MEDICINE.

1. Describe the symptoms and give cause, treatment, and prognosis of Addison's disease (disease of suprarenal capsule).
2. Give the cause, diagnosis, symptoms of purulent inflammation of the bile passages (suppurative cholangitis).
3. Etiology, symptoms, signs, and treatment of a large pleural effusion.
4. What are the chief dangers and common complications of diabetes mellitus?
5. Causes, diagnosis, duration, and treatment of peripheral neuritis.
6. To what class of diseases does chorea belong? Give treatment and name any important complication.
7. Give the treatment of mucous colitis.
8. Give the prognosis and treatment in cases of aortic regurgitation with general arteriosclerosis.
9. Give treatment and prognosis in chronic contracting nephritis (interstitial).
10. Give treatment of acute endocarditis.

GYNECOLOGY.

1. State upon what grounds you would base your preference for an abdominal or a vaginal hysterectomy.
2. Describe the operation of trachelorrhaphy.
3. What do you understand by the so-called cervical erosions?
4. Stenosis of the cervix; give the etiology, symptoms, and treatment.
5. What do you understand by vicarious menstruation?
6. Describe the pathological changes in chronic ovaritis.

LARYNGOLOGY AND RHINOLOGY.

1. Give the pathology of croupous laryngitis.
2. Give the appearance, symptoms, and treatment of follicular tonsilitis.

MEDICAL JURISPRUDENCE.

1. Differentiate between cerebral apoplexy and acute alcoholism.
2. What is paranoia?

PHYSICAL DIAGNOSIS.

1. Give symptoms and prognosis of lymphadenoma.
2. Give etiology, symptoms, and prognosis of pneumothorax.
3. Give differential diagnosis between organic hemiplegia and hysteric hemiplegia.
4. Give symptoms of acute synovitis of knee joint.
5. Give differential diagnosis between squamous eczema, psoriasis, and seborrhea.

OPHTHALMOLOGY AND OTOLOGY.

1. Give complications of middle ear disease.
2. Give treatment of chronic purulent otitis media.
3. Give symptoms and treatment of iritis.

PEDIATRICS.

1. How would you treat abdominal pain in infants?
2. Give the prognosis of the following diseases in infants (taking the age factor alone in consideration), lobar pneumonia, bronchial pneumonia, and whooping cough.

OBSTETRICS.

1. Define abortion, mention the dangers, and give treatment following abortion.
2. Give symptoms of placenta prævia. What is the immediate danger of this condition?
3. What are the causes of puerperal albuminuria? What is the treatment?
4. What are the most serious complications met with in breech presentation?
5. What are the causes of nausea and vomiting in pregnancy? What is the treatment?
6. In case of hemorrhage in the third stage of labor, what is the necessary treatment?
7. What is phlegmasia alba dolens? At what time does it usually occur? What is the treatment?
8. Describe the uterus, its normal position, its relationship to other organs, and means by which it is held in place.
9. What are the diagnostic symptoms of pregnancy before the fourth month? After the fifth month?
10. What would you do in case of rupture of the uterus in the first stage of labor? In the second stage?

SURGERY.

1. Give the indications for operation in compound fracture of the thigh, and describe the operation in detail.
2. State the symptoms of fracture of the surgical neck of the humerus, and detail an approved treatment.
3. Give the early symptoms and treatment of hip-joint disease.
4. Describe the symptoms of cerebral compression and concussion, and detail the treatment for each.
5. Enumerate conditions in which you would administer ether in preference to chloroform.
6. Give early symptoms of caries of the vertebra. (Pott's disease).
7. Diagnose pyonephrosis.
8. Give treatment for retention of urine in male patient after catheterization has failed.
9. Differentiate between appendicitis (catarrhal), salpingitis, and ovaritis.
10. Name the clinical varieties of abdominal hernia.

MATERIA MEDICA AND THERAPEUTICS.

1. Name the chief classes of diuretics, and give indications for use.
2. Under what circumstances would you employ the following and why? Give dose of (a) strychnine (sulphate), (b) calomel, (c) asparagin, (d) aconite (tincture.)
3. Name several substances which *lower* blood pressure and give indications for their employment.
4. Name several substances which *raise* blood pressure and state when you would use them.
5. Give dose and action and therapeutic indications for the following: Atropine, pilocarpine.
6. Give therapeutic classification and dose of the following: (a) Potassium bromide, (b) male fern, (c) arsenious acid, and (d) gentian (co. tincture).
7. Describe the physiological action of one of the preparations of calcium used in medicine.
8. Describe the general indications for the use of liniments and name some of the drugs so employed.
9. Describe the different methods of employing mercury in syphilis.
10. Dose and use of physostigma.

PATHOLOGY.

1. Describe the process of fatty degeneration.
2. Define the terms "malignant" and "benign." What features of an abnormal growth render it abnormal?
3. Give the pathology and varieties of goiter.

4. Describe the formation of pus. What are some of the phenomena attending pus formation?
5. What are the pathological changes in emphysema of the lungs?

BACTERIOLOGY.

1. Describe the gonococcus and give the pathological changes due to gonococcic infection.
2. Describe an approved method of obtaining cultures of the diphtheretic bacillus.
3. What pathological conditions may be produced by the colon bacillus?
4. Describe toxins, antitoxins, and ptomains.
5. Define immunity. What do you understand by acquired immunity.

CHEMISTRY.

1. What is valency?
2. What characteristic reaction would ozone or hydrogen dioxide have on potassium iodide?
3. Complete this formula: $Na_2SO_4+2C+CaCO_3=$
4. What is formed by treating hydrochloric acid with manganese dioxide?
5. Complete this formula: $K_2O_3+2C=$

ETIOLOGY AND HYGIENE.

1. What is the etiology of lobar pneumonia?
2. What do you believe to be the most frequent cause of excessive secretion of HCl in the stomach?
3. What is the etiology of progressive muscular atrophy?
4. How should an epidemic of bubonic plague be managed in order to prevent the spread of the disease?
5. What measures would you recommend as the most efficient way of preventing malaria?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

October 23-25, 1907.

PHYSIOLOGY.

1. *Functions of the pneumogastric nerve*: "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

2. Blood pressure is the pressure on the blood due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries.

Various conditions may contribute to cause alteration in the blood pressure; thus if the heart beats more quickly, or more vigorously, the blood pressure is raised; a similar condition occurs from the contraction of the arterioles. The reverse of each of these conditions lowers the blood pressure.

3. There are two theories of color vision, as follows: "(a) The *Young-Helmholtz theory,* which assumes that there are three fundamental sensory elements in the retina which correspond to and are stimulated primarily by the primary colors—red, green, and violet; also that each color-perceiving element is slightly stimulated by others of the spectral rays. When red rays fall upon the retina they stimulate the red-perceiving elements strongly and the green and violet very feebly. The resulting sensation is that of red. So also is it with green and violet rays. When the retina is stimulated by both red and green rays the two corresponding color-perceiving elements are strongly stimulated. The resulting color perception, however, is a combination of the two sensations and corresponds to some region of the spectrum between the red and green, according to the relative intensity of the two stimuli. When all three color-perceiving elements are stimulated at the same time this theory assumes that white light will be perceived. In a similar manner all the various color sensations are arrived at.

(b) *Hering's theory,* which is based on the assumption that there are chemical substances in the retina, photogenic substances, which are stimulated by the colors of the spectrum. It assumes three photogenic substances which are called the red-green, the yellow-blue, and the white-black substances. By this theory, when the red-green substance is stimulated by red or green light, respectively, the former produces destructive or catabolic changes, the latter constructive or anabolic changes, in the substance. When red light falls upon the retina it produces catabolism in the red-green substance, which in turn develops a nerve impulse that arouses the sensation of red. When green light, on the other hand, stimulates the retina, it produces anabolism of the red-green substance and the sensation of green. The same rule holds with the other two substances. It will be noticed that this theory is based on the complemental colors." (From Kirkes' *Physiology.*)

5.—

SECRETIONS.	DIGESTIVE PRINCIPLES.	FUNCTION.
Saliva.....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric juice...	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

Bile contains an amylolytic ferment which has a slight action on starch; it also aids in the digestion, emulsification and absorption of fats.

6. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Anabolic, or constructive, and (2) catabolic, or destructive.

7. The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

ANATOMY.

1. The macula lutea is situated on the inner surface of the retina, at the posterior pole of the eyeball, right in the center, and hence directly in the axis of the globe.

3. The clavicle commences to ossify before any other bone.

4. The sternum is divided into: (1) The manubrium, (2) the gladiolus, and (3) the ensiform or xiphoid appendix.

Nine pairs of muscles and one single muscle are attached to the sternum.

7. If the ligature is applied *above* the origin of the Superior Profunda: The Posterior Circumflex and the Subscapular, by anastomosing with the ascending branches of the Profunda, carry on the circulation.

If the ligature is applied *below* the origin of the Superior Profunda: The Superior Profunda and its branches anastomose with the recurrent branches of the Radial, Ulnar, and Interosseous, and thus carry on the circulation.

10. The tonsil is separated from the internal carotid artery by the Superior Constrictor of the Pharynx

GYNECOLOGY.

1. As to preference between vaginal and abdominal hysterectomy, the following is taken from Garrigues' *Gynecology*: "If the vaginal route is available, it should be preferred, because it entails much less shock, requires a simple after-treatment, does not leave any visible cicatrix, predisposes less to hernia, and allows the patient to resume work in shorter time. On the other hand, the vaginal route is more difficult on account of the limited space. Hemorrhage is more troublesome to check, adhesions are harder to separate, and the bladder and intestine more exposed to injury and less accessible for repair. The pelvic cavity cannot be seen so well and the abdominal not at all. If tissue is left to mortify, it emits an offensive odor."

5. *"Vicarious menstruation":* This is a flow of blood from some other organ recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the

mammary glands, ulcerated surfaces, and many other parts." (King's *Manual of Obstetrics.*)

MEDICAL JURISPRUDENCE.

1. In *cerebral apoplexy*: There is generally paralysis of the head and upper limbs; and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

In *acute alcoholism*: The patient can generally be aroused; the coma is not, as a rule, complete; the face may be flushed; the pupils are normal or dilated; the respirations are normal in frequency, but deep; the skin is cool and moist, and the body temperature may be below normal.

2. *Paranoia* is a primary chronic form of insanity, occurring especially in degenerates, and marked by hallucinations and delusions which are systematized, *i.e.* exhibit a logical connection and sequence, so that the patient from his perverted ideas, in which he firmly believes, draws logical and coherent influences. (From Duane's *Medical Dictionary.*)

OBSTETRICS.

2. The *symptoms* of placenta prævia are: Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse.

The *immediate danger* is death of the mother from hemorrhage.

4. The most serious complications met with in breech presentation are: Extension of the head or of the arms over the head; compression of the umbilical cord; premature respiration or asphyxiation of the child; the child may also suffer from paralysis, hemorrhage, fracture, or dislocation.

6. "In the presence of actual hemorrhage the treatment varies according as the placenta is still within the uterus or has already been expelled. In the former case the uterus should at once be grasped through the abdominal wall and firmly kneaded. If firm contractions come on, all is well, but if the hemorrhage continues and the uterus relaxes as soon as the kneading is stopped, the placenta should be expressed by Credé's method; and if this cannot be accomplished and the patient's condition is alarming, manual removal may become necessary. . . . . If the hemorrhage does not cease after the delivery of the placenta, the cause should be ascertained and suitable treatment instituted. Tears should be located and their edges brought together by sutures. On the other hand, if the hemorrhage is the result of the retention of placental tissue, the carefully disinfected hand should be carried up into the uterus in order to seek for and remove the retained cotyledon. Under such circumstances the hand acts as a most efficient irritator, causing the uterus to contract energetically. After separating the retained portion of the placenta the hand should not be withdrawn at once, but should be allowed to recede gradually as it is forced down by the contraction of the fundus. If the hemorrhage is due to atony, the uterus should be vigorously kneaded, and from forty to sixty minims of ergot or of ergotol administered hypodermically. . . . . If these measures are not attended with the desired result, a very hot intrauterine douche of several liters of sterile salt solution should be employed. . . . . If the hemorrhage persists in spite of the douche, our only hope of controlling it is by packing the uterus tightly with sterile gauze. Before resorting to the use of the pack it is always advisable to palpate the interior of the uterus, as occasionally a portion of the placenta may have been retained, even though immediately after expulsion the organ may have apparently been entire." (Williams' *Obstetrics.*)

SURGERY.

3. *The early symptoms of hip-joint disease* are: Night cries (in a child); lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

Treatment: In the early stages, rest in bed is indicated, with extension; also tonics, restoratives, fresh air. If necessary, the limb should be straightened and put up in plaster-of-Paris, or a brace or other mechanical appliance should be used. Intraarticular injections of iodoform have been recommended. Resection of the hip may be necessary.

4.—

CONCUSSION OF THE BRAIN.	COMPRESSION OF THE BRAIN.
Unconsciousness is incomplete; patient can be made to answer, though it may be briefly, and in simple words.	Complete unconsciousness; may scream into patient's ear at the top of the voice, but will receive no answer.
Special senses, though greatly blunted, are not abolished.	Special senses entirely suspended.
Power of movement not destroyed; if the position of a limb be changed the patient will resist or bring it immediately into the original position.	Complete or partial paralysis; in most cases hemiplegia.
Respiration is quiet and feeble.	Respiration full and noisy.
Pulse feeble, frequent, and intermittent.	Pulse full and slow, and sometimes laboring.
The stomach sickens and rejects its contents.	The stomach is insensible to any impression; no nausea or vomiting.
The feces may be discharged incontinently, as may also the urine, though not usually.	Bowels are torpid, and the bladder incapable of emptying itself, though the urine may escape by overflow.
Deglutition little impaired.	Deglutition difficult or impossible.
Pupils variable, though generally contracted; the eyelids somewhat open.	Pupils variable, though generally much dilated, and the eyelids closed.
Temperature of the body less than natural.	Temperature almost natural, a little below the normal standard.

(From Treves' *Manual of Surgery.*)

5. "*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic." (Hare's *Practical Therapeutics.*)

6. The early symptoms of caries of the vertebra are: Pain in the back, which is made worse by movement or pressure; muscular spasm; chronic bilateral belly-ache; the patient easily tires, keeps the back rigid, and constantly rests; torticollis may be present; and the patient may support the head with his hands.

7. *Pyonephrosis* may be diagnosed by: The presence of pus in the urine, which may be constant or intermittent; some obstruction to the flow of urine; sepsis; a tumor in the loins; the use of the cystoscope and ureteral catheter will aid in the diagnosis.

8. The bladder should be punctured above the pubes.

9. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle; there are usually fever, nausea, vomiting, and constipation.

Salpingitis is diagnosed by: A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

The most common cause is infection, either gonorrheal or puerperal.

In *ovaritis* the pain is not localized, but spreads to the vagina and rectum; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

10. The clinical varieties of abdominal hernia are: Reducible, irreducible, obstructed or incarcerated, inflamed, and strangulated.

MATERIA MEDICA AND THERAPEUTICS.

1. Diuretics are classified as: (1) Hydragogue diuretics, (2) stimulant diuretics, and (3) refrigerant diuretics.

Diuretics are employed: (1) To remove excess of fluid from the tissues, as in dropsy; (2) to dilute the urine; (3) to promote the elimination of waste products or poisonous material from the blood, and (4) to maintain the action of the kidneys.

3. Substances which *lower* blood pressure: Opium, aconite, antimony, dilute hydrocyanic acid, ipecac, chloral, chloroform, veratrum, potassium.

4. Substances which *raise* blood pressure: Alcohol, digitalis, ether, strychnine, ammonia, strophanthus, camphor, squill.

5. Atropine: *Dose,* gr. 1/160.

Action: Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Therapeutic Indications: For the relief of pain, to dilate the pupil, to check secretions, for diarrhea, for asthma, for shock and collapse, for colic of all kinds, for delirium, for epilepsy, chorea and migraine, for paralysis, for cough, in constipation, in chorea, spermatorrhea, or cystitis.

Pilocarpine: *Dose,* gr. 1/5.

Action: Stimulant of secretory nerves and of involuntary muscles, myotic, nervous depressant, sudorific.

Therapeutic Indications: In Bright's disease, uremia, and whenever a prompt diaphoresis is required.

6.—

	Therapeutic Classification.	Dose.
(*a*) Potassium bromide.	Nervous depressant.	gr. xv.
(*b*) Male fern.	Anthelmintic.	gr. lx.
(*c*) Arsenious acid.	Tonic or restorative.	gr. 1/30
(*d*) Gentian (co. tincture.)	Stomachic.	ʒj.

9. Mercury is employed in syphilis in the following ways: (1) inunction, (2) by mouth, (3) hypodermically, (4) fumigation.

10. Physostigma: *Dose,* gr. jss.

Use: "Atony the bladder and intestines; gastric and intestinal dilatation; flatulence; chronic respiratory affections; tetanus; trismus neonatorum and other spasms; epilepsy; chorea; as an antidote in strychnine poisoning. Physostigmine is used locally in ophthalmic practice." (Wilcox, *Materia Medica.*)

8. *Liniments* are used for the relief of local pain, for superficial neuralgias, as stimulants and rubefacients, to abort beginning inflammations, for rheumatism, bruises, sprains, for some local skin affections.

Some of the drugs so employed are: Aconite, ammonia, alcohol, camphor, belladonna, lime, linseed oil, cotton seed oil, chloroform, mercury, opium, soap, turpentine.

BACTERIOLOGY.

3. "The *bacillus coli communis* is associated with many diseases especially of the abdominal organs, though it is not positively known what etiological relation, if any, it bears to these affections. It has been found in peritonitis, appendicitis, cystitis, urethritis, pyelonephritis, etc. The colon bacillus has been assumed to be the cause of cholera nostras and cholera infantum. . . . Puerperal fever is not infrequently due, in part at least, to infection of the vagina or uterus by the colon bacillus. Other diseases to which this organism seems to stand occasionally in relation are endocarditis, meningitis, tropical abscess of the liver, bronchopneumonia, fetid bronchitis, amygdalitis, etc. In these diseases the *Bacillus coli communis* has been found sometimes alone, but usually associated with other pathogenic bacteria in such numbers that it must be considered a factor in the etiology of the affections, and in some cases there is reason for belief that it may be the primary cause." (*Reference Handbook of the Medical Sciences.*)

(4) *Toxins* are the poisonous products of pathogenic bacteria or of ptomaines or leucomaines.

Antitoxins are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

Ptomaines are the putrefaction products of dead animal tissues or fluids.

5. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Acquired Immunity is this resistance acquired: (1) by a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are:—(1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

CHEMISTRY.

1. Valency is the combining power of an atom of an element as compared with that of an atom of hydrogen.

2. Ozone or hydrogen dioxide decomposes solutions of potassium iodide, with liberation of iodide and formation of potassium hydroxide.

$$H_2O_2+2KI=I_2+2KOH$$
$$O_3+H_2O+2KI=I_2+2KOH+O_2$$

3. $Na_2SO_4+2C+CaCO_3=Na_2CO_3+2CO_2+CaS$.

The reactions really are:—

$$Na_2SO_4+2C=Na_2S+2CO_2$$
and $$Na_2S+CaCO_3=CaS+Na_2CO_3$$

4. Manganese chloride, chlorine, and water are formed when manganese dioxide is treated with hydrochloric acid:

$$MnO_2+4HCl=MnCl_2+Cl_2+2H_2O$$

5. $K_2O_3+2C=K_2+CO_2+CO$

ETIOLOGY AND HYGIENE.

1. Lobar pneumonia is due to the invasion of the lung by pathogenic bacteria, chiefly the *Diplococcus pneumoniæ.*

Lowered vitality, exposure to wet and cold, and alcoholism are all predisposing factors.

2. The most frequent cause of excessive secretion of HCl in the stomach is probably either (1) mental overwork or worry, or (2) alcohol or highly spiced food.

3. Progressive muscular atrophy is supposed to be due to syphilis, exposure, or overexertion.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	Ancil Martin, Phoenix	Phoenix	April 6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April 14

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

South Dakota.—The Board of Medical Examiners, in its classification of diplomas, recognizes only such medical colleges as require, as a condition of admission, the equivalent at least of a standard high school education; it demands also the full four years' attendance in the medical college. The requirement of preliminary education will be raised after 1910, when there will be demanded at least one year in a college of liberal arts, or its full equivalent.

City, for the week ending February 8, 1908:

Surgical Suggestions.

Circumcision.—The following technique is recommended by Mark H. Rogers: The operation should be performed on the eighth or tenth day without anesthesia. The baby should be hungry and allowed to nurse a "sugar teat" during the operation. This latter procedure is a very great aid; a hungry infant sometimes forgetting to cry at all. All of the infant's clothes are removed except the shirt. The nurse now stands at the head handling the "sugar teat" and holding the hands. An assistant holds the feet. The foreskin is drawn well down, clamped with a slot phimosis forceps and held firmly while the foreskin is severed quickly through the slot with a sharp bistoury. I next split the dorsal skin of the penis for perhaps one-quarter or three-eighths of an inch. This prevents the possibility of a tight ring remaining behind the glans. Next I seize the mucous membrane with a very small self-locking forceps, such, for example, as oculists use for the conjunctiva. I then split the mucous membrane with a dorsal incision clear to the glans, separate the adhesions with a probe and remove smegma; then with one or two snips of the scissors remove the mucous membrane, first on one side, then on the other, cutting from before backwards. Three or four No. 1 sterilized catgut stitches are now inserted, care being taken to take up the bleeding points, and the operation is completed. Cocaine anesthesia is exceedingly dangerous for babies.—*The Dietetic and Hygienic Gazette.*

Methods Against Fleas.—L. O. Howard says the following have been recommended: Fill a soup-plate with soapsuds; in the center place a glass of water with a scum of kerosene on top; place the soup-plate on the floor in an infested room, and set fire to the kerosene at night. Fleas in the room will be attracted and will jump into the soapsuds. It is also said that houses may be rendered immune by dissolving alum in the whitewash or kalsomine applied to the interior walls, putting sheets of thick paper that have been dipped in a solution of alum under the floor matting and scattering pulverized alum in all crevices where insects might lodge or breed. Powdered alum may be sprinkled upon carpets already laid and then brushed or swept into their meshes with no injury to the carpets and with the certainty of banishment to many insect pests, including both moths and fleas. Sheets that have been soaked in alum water and then dried may profitably inclose those that are spread nearest to the sleeper.—*Science.*

Urethral Hemorrhage.—Valentine and Townsend say that in hemorrhage from the anterior urethra blood may appear at the meatus or ooze or stream therefrom or may drip after urination. This bleeding is usually not associated with pain, nor is it forcibly ejected by the detrusors, as it is in the terminal hemorrhage of posterior urethritis. In an anterior urethral bleeding the first urine usually is bloody, the second may be clear, and the last blood-tinted or clear. The treatment of anterior urethral bleeding premises removal of foreign bodies or growths if present. If the bleeding does not then spontaneously stop, rest, opium, camphor monobromate, and compression must be prescribed. The easiest and most effective compression is attained by bandaging a soft catheter along the lower surface of the penis, between the corpora cavernosa. Hemorrhage from the posterior urethra usually begins with the end of urination and follows the act. Blood may be also admixed in the last urine or drip or be forced from the urethra after urination. Posterior urethral bleeding is usually associated with and followed by pain. Hemorrhage from both urethræ most frequently occurs in peracute gonorrhea, after violent instrumentation and injudiciously employed injections and irrigations. When due to gonorrhea it must be treated by irrigations, plus rest and according to the other directions usually given.—*American Journal of Urology.*

Strangulated Hernia.—Allison says of this condition that a two-stage operation affords greater security than the theoretically more attractive procedure of primary bowel-resection and radical cure. Lavage, and persistent, low pressure, normal-salt enemata, and a moderately elevated position supplement, in the most satisfactory way, the surgical measures. If anastomosis be deemed advisable as a primary operation (we think this is rare), the lateral operation is considerably safer, and this procedure, moreover, will meet the indications more safely in a majority of those cases requiring the secondary operation after an artificial anus has been established. The post-operative dangers of ileus are many, and in strangulated hernia the hope of escaping them by delay is groundless, thus differing relatively from the usual obstructive symptoms of appendicitis.—*Journal of the Minnesota State Medical Association.*

Medical Items.

Health Report.—The following cases of **smallpox, yellow fever, cholera, and plague** have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending December 20, 1907:

SMALLPOX—UNITED STATES.

SOME NOTES ON THE ETIOLOGY, PROPHYLAXIS AND THERAPEUTICS OF LARYNGEAL TUBERCULOSIS.

INCLUDING SOME CLINICAL EXPERIMENTS WITH BIER'S CONGESTIVE HYPEREMIC TREATMENT.*

BY S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; ATTENDING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK, ETC.

AND

ARTHUR J. HUEY, M.D.,

NEW YORK.

ATTENDING LARYNGOLOGIST TO THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

IT goes without saying that in the short space of time allotted to us any contribution to the subject of this evening's symposium must necessarily be limited, and the field cannot be covered in its entirety. All we hope to be able to do is to bring out a discussion on a few perhaps less known points regarding the etiology, prophylaxis, and treatment of laryngeal tuberculosis and learn whether what we think we have observed and learned in our limited experience can be corroborated by the experience of the masters in laryngeal practice present here to-night.

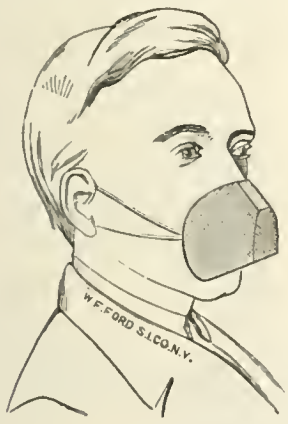

FIG. 1.—Beverley Robinson's Zinc Inhaler.

The cases of absolutely primary laryngeal tuberculosis are comparatively rare, as you all know, and we may leave them entirely out of consideration. It would seem that among those who develop secondary tuberculosis there are more male than female patients. Among the men, those who have been addicted to alcoholism are more frequently attacked by the laryngeal invasion than those who have been very moderate drinkers or total abstainers. Syphilis, too, seems to predispose to the secondary tuberculous invasion of the larynx.

Among the professions whose members, when afflicted with pulmonary tuberculosis, develop laryngeal tuberculosis more readily, we must mention teachers. This was first statistically demonstrated several years ago by Orâscu.[1] Long-standing laryngeal catarrhs, from whatever cause, render the pulmonary invalid more susceptible to a laryngeal tuberculous invasion. We have not been able to find any reliable statistics concerning trades which predispose to laryngeal tuberculosis more than to pulmonary tuberculosis in general. There is, however, no doubt in our minds that all patients who either from causes of obstruction in the upper respiratory tract, because of long-standing dry catarrh of that region, from a purely nervous cause, or because of lack of training, are in the habit of constantly irritating their throats by dry cough, are certainly more disposed to develop a laryngeal tuberculosis than those who have none of the just enumerated causes for a chronic irritating cough.

As long as the epithelium is intact it furnishes a strong protection against the entrance of the tuberculosis bacilli. But this constant irritation is very apt to produce a slight erosion. This may not always be visible to the naked eye, but will be large enough to permit the bacilli to enter into the deeper tissue.

In saying this, however, we do not wish to be understood as not admitting that a very large number of tuberculous invasions have their origin from the bacilli coming from within, pushing from the subepithelial cellular layer out in the intercellular lymph passages of the epithelium towards the periphery.

On the other hand, the statement that continued dry and irritating cough not treated or not controlled tends to develop laryngeal tuberculosis, is

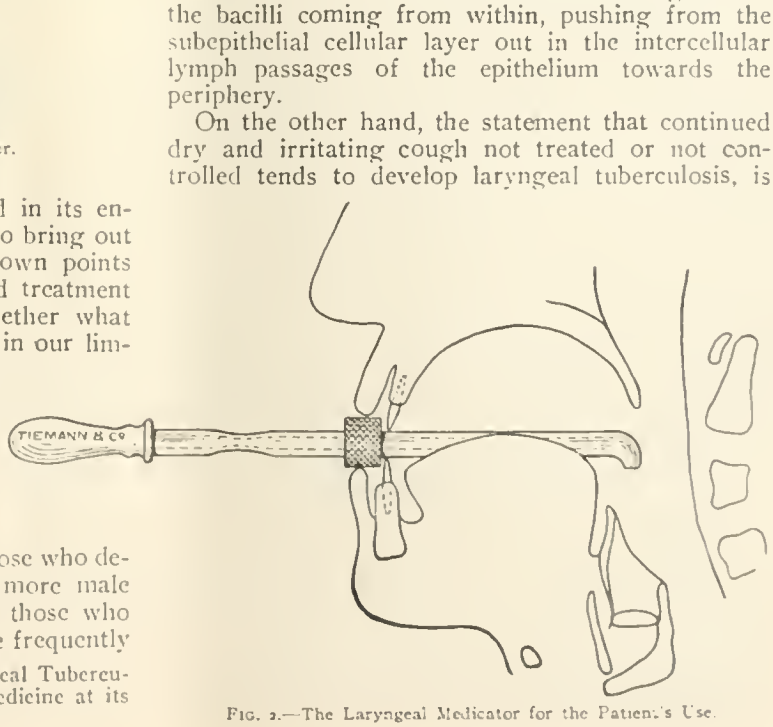

FIG. 2.—The Laryngeal Medicator for the Patient's Use.

*Contribution to the Symposium on Laryngeal Tuberculosis, read at the New York Academy of Medicine at its stated meeting, January 16, 1908.

borne out by the fact that in sanatoria where every cough without expectoration is treated, and most often successfully, either by removal of the physical cause, by proper medication, and above all by discipline, largyngeal tuberculosis develops much more rarely than among patients either not treated or not sufficiently trained in this regard.

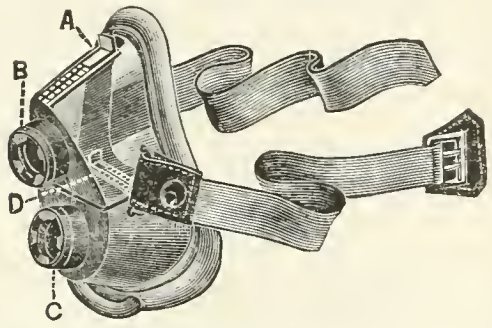

Fig. 3.—The Kuhn Suction Mask for the treatment of pulmonary and laryngeal tuberculosis.

Now, what can be done to prevent the development of the laryngeal complication, considering the little light we seem to have regarding the etiology? First of all every case of pulmonary tuberculosis should be examined for possible laryngeal complication, particularly when the patient has followed an occupation demanding the continued and excessive use of the voice. The old and recent syphilitic should be treated by vigorous specific medication; the alcoholic should be told that the continued use of liquor will aggravate his condition and be apt to produce a laryngeal tuberculosis. Laryngeal and pharyngeal catarrhs in the pulmonary patient, whether dry or moist, should be carefully treated.

When the patient is a mouth-breather the cause of this condition should be looked into and obstructions removed, however, with as limited surgical interference as at all possible, for we must bear in mind the possibility of an infection of nose and pharynx as well. All patients in danger of laryngeal tuberculosis should be enjoined to use their voice as little as possible, to avoid conversing when walking or riding against the wind, and always to breathe with the mouth closed.

No tuberculous patient should leave the office of the examining physician without being thoroughly informed of the danger to himself and to others of unnecessary coughing. By unnecessary cough we understand the so-called dry cough, which the populace considers innocent. Unless the patient holds his hand or handkerchief before his mouth, the droplets which he expels during the so-called dry cough may be bacilliferous and a drop infection may ensue. Patients should be told that this drop infection may be the means of infecting someone else. But perhaps a greater impression may be made upon the pulmonary invalid if he is told that by controlling the unnecessary cough he will lessen his chances of ever having a laryngeal complication. He will surely improve his general condition by disciplining himself, that is to say, coughing only when he has to expectorate and suppressing all useless cough, that is to say, the dry cough.

How can we aid the patient when most of his cough is purely a matter of habit and he has the willingness to discipline himself? The patient should be taught to realize that the expectoration is drainage and must come up. He should never, out of false modesty, swallow the expectoration nor suppress its coming up. To facilitate as far as practicable the ejection of the accumulated secretions of the night, it is well to advise the patient to take a hot orangeade or lemonade on retiring and again in the morning before rising. Toward morning the pillow should be removed and the patient should lie flat on the bed, the foot end of the bed somewhat raised so as to produce a modified Trendelenburg position. This is for the purpose of allowing the secretions to reach the upper pulmonary and bronchial portions and thus become more easily ejected. Such and similar positions have been devised by Jacoby and Weicker to produce hyperemia of the lungs without the aid of any other appliance. We will speak of this new method of treating tuberculosis of the respiratory organs later on, but desire to mention here that in a recent communication to Dr. Knopf Dr. Weicker admits the failure of influencing the pulmonary circulation through such positions. On the other hand, he emphasizes the value of elevating chest and extremities ("Flachliegekur" or "Hochlagung des Unterkörpers") as a means to facilitate expectoration and to diminish cough. It must be evident that the greater amount of freedom from cough thus produced not only adds to the comfort of the patient but must be conducive to cure.

A few deep respiratory movements may also be helpful in ejecting the accumulated matter and thus accomplishing a drainage, rendering the patient relatively free from cough and dyspnea during the greater part of the day. If the modified Trendelenburg position becomes too uncomfortable a small pillow may be placed under the head. If in spite of these precautions to drain the lungs of the accumulated moterial the irritating cough reappears during the day, occasional sips of liquid (milk or water) will help him to control the impulse to cough. Another good way to stop the reflex producing the irritating cough is to take a quick short inhalation at the moment the irritation is felt. This short, quick inspiratory movement has in our experience been able to do more to control the useless cough than anything else.

Fig. 4.—Patient breathing through the Kuhn Suction Mask.

The more energetic medications, such as intratrachial injections, typical cough mixtures or expectorants, or lozenges containing the ammoniamuriates and opiates, such as morphine, codein, heroin, etc., we will not discuss here. Of only one medicinal method of helping to control cough would we like to make mention, it is the use of an inhalation composed of equal parts of menthol, eucalyptus oil, and spirits of chloroform. Ten to fifteen drops placed on a Beverley Robinson Zink Inhaler and worn from 20 to 30 minutes at a time, 4 to 6

times in 24 hours, will certainly help to allay a cough in pulmonary or laryngeal tuberculosis. We take pleasure in showing you here the latest model of this very practical and useful invention (Fig. 1). When the patient cannot conveniently make use of the inhaler he may drop the prescribed quantity of the mixture on his handkerchief and thus inhale it.

As has been said in the introduction to this contribution, we do not intend to speak of the various methods in vogue for the treatment of laryngeal tuberculosis. The local application of lactic acid in various strengths has its advocates and has been decried by others as useless and too painful. The same may be said of curettage. Orthoform seems to have met with more general favor. All laryngologists agree on the absolute necessity of local anesthesia sufficient to enable the patient to eat when deglutition has become painful. Orthoform in form of an emulsion or the new hydrochlorate dissolved in plain water, seems to be particularly useful for that purpose and to be preferred to other drugs because of its relative harmlessness with good anesthetic and antiseptic properties.

The "Patients' Laryngeal Medicator," devised by Dr. Yankauer upon the suggestion of Mannheimer of New York, is an instrument to be recommended for the purpose of applying the orthoform solution particularly when the patient cannot be seen daily by the physician. This instrument is described in the Transactions of the National Association for the Study and Prevention of Tuberculosis of 1907 in the following words by Dr. Mannheimer:

"It is a long medicine-dropper, made of heavy glass, so-called barometer-tubing, bent at the lip (Fig. 2). Just in front of the rubber bulb* are two depressions which, when pointing upward and downward, indicate that the tip is turned downward. Each patient has to be shown how far to introduce the instrument, *i.e.* just behind the uvula. At that point a strip of adhesive plaster is wound around the tube. The patient introduces the filled instrument up to that point, holds it firmly between the teeth, takes a deep inspiration, and compresses the bulb. Some patients have to hold the head slightly forward, others slightly backward. I have repeatedly convinced myself that the fluid really reaches the larynx by injecting colored solutions of cocaine or emulsions and then examining with the laryngoscope. Experienced patients usually know when the medicine 'gets there.'

"The instrument can be used for watery and oily solutions. It is especially adapted for dispensary and private practice, *i.e.* for all patients who are not under constant medical supervision and care. If such patients can anesthetize their own larynx by means of orthoform or anesthesia emulsions, they relieve their distressing dysphagia and are thus enabled to feed properly, thereby fulfilling one of the first requisites in the cure of their disease.

"I have no doubt that many of you have taught your ambulatory patients to medicate their own larynx by means of sprays or powder-blowers, but this instrument has the advantage of being simple, clean, effective, and cheap. It costs 25 cents. It is made by Tiemann & Co., and called 'the patient's laryngeal medicator.'"

Because of the painfulness of laryngeal tuberculosis we should do everything we can to render the patient comfortable, and for this reason we recommend the use of this tube and the use of the orthoform because it is safe for the patient to use it himself and he can relieve himself quickly of often excruciating pains. When desirable the orthoform may be mixed with iodoform in equal proportions and with the aid of the yolk of an egg a suitable emulsion made.

We cannot offer anything new regarding the climatology in laryngeal tuberculosis. Some patients seem to do particularly well in warm and moist climates; not all are benefited by high altitudes; however, pure air, sunshine, and absence of strong winds seems favorable to the laryngeal tuberculous invalid, particularly when such favorable climatic conditions can be combined with a careful local and constitutional treatment.

In far advanced cases of laryngeal tuberculosis, unless the patient himself insists on going away from home, it would seem cruel and useless to add banishment and nostalgia to his suffering.

In prescribing the outdoor treatment in cold weather for a pulmonary invalid with considerable laryngeal involvement the same humane consideration should guide us. Unless he feels better outdoors and likes the cold we should not insist upon his taking the outdoor treatment in cold or unpleasant weather.

Laryngeal cases, in the earlier stages with relatively little pulmonary involvement, are often benefited by a change to a moderately high or to a warm moist climate with between 500 to 1,500 feet of altitude, particularly when there is a chronic feeling of dryness in the throat. When there is a tendency to moist catarrh, even the very dry and hot climates, provided dust storms are not frequent are often beneficial.[2]

Sunlight alone has been used as a therapeutic agent in laryngeal tuberculosis by Sorgo of Alland, who had treated a number of cases and claimed good results by using a reflector and by applying the reflected rays directly to the lesions.[3] Whatever doubt we may have as to the local effect of the rays of the sun on the laryngeal tuberculous lesions, so much is certain that this class of patients feel better when the sun shines than in stormy and cloudy weather, and the recent attempt of some authorities to decry sunlight and declare it dangerous in phthisiotherapy may be considered, to say the least, as unwise.

There is no doubt that, in tropical countries, the newly arrived person who has been born and raised in northern climes, be he blond or brunette, unless he leads an exceedingly sober and careful life, and protects himself against the strong actinic rays and the intense heat of midday, is bound to suffer and become more easily the victim of endemic and epidemic diseases. But to apply this rule to our temperate zones and northern climates is fallacious, unscientific, and even dangerous. It has been demonstrated again and again that in our moderate zones the patients in the general hospitals do best in those wards which have the most exposure to the all-beneficent sun. The celebrated health resort, Davos Platz, in Switzerland, to which thousands of consumptives flock every year, owes its reputation mainly to the great amount of sunshine characteristic of that region. And may we not say the same of our equally world-famous climates of Colorado, New Mexico, Southern California and some of our Southern States, where the number of sunny days each year amounts often to three hundred and more? On the other hand, recent reports show that in England the mortality from tuberculosis is highest in places where weather statistics show the

*We have since experimented with this excellent little instrument, but found the bulb too small to express any emulsion with sufficient force. To enlarge the bulb to twice its size would, in our opinion, enhance the value of the instrument. We communicated this suggestion to the inventors and they have come to the same conclusion as we have. They will see to it that a larger bulb will be attached to the instruments hereafter manufactured

greatest number of rainy, windy and cloudy days,[4] and here in New York it has been demonstrated that there is more sickness from pulmonary and bronchitic disease on the north side of the street than on the south, where the house gest more sunlight.

Sanatoria with good hygienic environment seem to be best adapted for the management of laryngeal tuberculosis. Unfortunately, because of the unfavorable prognosis in the majority of such cases, sanatoria do not like to take patients with laryngeal complications. It would almost seem that there is a need of separate sanatoria which will make the treatment of laryngeal tuberculosis a specialty.

Before speaking of our clinical experiment with Kuhn's mask, we may be permitted to say one word on diet. Neither solid nor absolutely liquid foods are indicated when deglutition is painful. A bland diet composed of gruel, toast of whole wheat bread soaked in milk, raw scraped beef with little or no seasoning, and soft boiled eggs is perhaps the best and most nutritious, and one which causes least discomfort in deglutition.

The claims of good results obtained from Bier's hyperemic treatment in pulmonary tuberculosis induced us recently to make a series of experiments in laryngeal tuberculosis with a view of determining whether or not laryngeal tuberculosis could likewise be benefited by Bier's treatment. As is known, Bier's treatment rests upon the theory that an artificial hyperemia can cure a tuberculous process. The truth of this has been demonstrated by the wonderful results of Bier's hyperemic treatment in osseous and articular tuberculosis.[5]

Why a hyperemia should cure tuberculosis is difficult to explain. It may be due to an increased phagocytosis or, if we apply Ehrlich's theory, it may be due to an increase of antibodies. If we are believers in opsonins the improvement may seem due to an increased opsonic index. Perhaps it may also be due simply to the increased carbonic acid gas we have in a venous stasis, and this gas may be deleterious to the growth of the bacilli.

Dr. Willy Meyer, in his recent article "Kuhn's Lung Suction Mask for the Hyperemic Treatment (Bier) of Pulmonary Tuberculosis,"[6] describes a mask used to attain the same end for tuberculosis of the respiratory organs in the following words:

"The construction of Kuhn's mask is based on Bier's original idea of having the patient inhale in a slightly obstructed manner, so as to produce negative pressure in the thoracic cavity. We know that the respiratory distention and contraction of the thorax is automatic, a physiological act. Now, if we prevent the easy filling with air of the elastic lung tissue, as is the case under ordinary circumstances, when the thorax expands during the act of inspiration, the air within the lungs is rarefied and the blood aspirated. In other words, we produce an artificial hyperemia of the lungs by suction.

"It was evident, however, that it would be an advantage to be able to increase or decrease this hyperemia by degrees, and it was with this point in view that Kuhn proceeded to construct his lung suction mask. Made of thin celluloid, the mask has the shape of the mouthpiece we use to cover the patient's face with when administering one of the volatile drugs for general anesthesia (Figs. 3 and 4). The edges here, too, are protected by rubber tubing which can be filled with air. The mask is divided transversely by means of a celllloid wall, which rests with its border on the upper lip. This border also is provided with an inflatable pad. In this way we have two separate cavities, one for the nose and one for the mouth, there being no communication except by a slide covering a narrow slit in the transverse dividing wall. This slit is opened only if nasal respiration is temporarily or permanently interfered with. The mask is placed over nose and mouth of the patient and held in place by two elastic straps passing below the ears and fastened in the back by means of a buckle. Another slide, attached to the outer side of the nasal section of the mask, controls the degree of obstruction desired. (Fig. 3—A). This is the principal part of the device, inasmuch as by it we regulate at will and by degrees the amount of obstruction to the passage of air into the alveoli of the lungs. It has a scale of 6°, and covers a slit somewhat less than 1-16 of an inch (1 millimeter) wide and somewhat longer than the one in the partition membrane between mouth and nose cavity. Two caps, that can be screwed off, each embracing a small celluloid plate, form the valve for expiration, same as we find this in the ordinary narcosis inhalers. (Figs. 3—B and C).

"If the regulating slide be entirely open, the patient can inhale quite some air, but naturally never as much as without the mask.

"Inspiration is done through the nose and expiration either through the mouth alone or through both mouth and nose.

"Of course, if desired, the valve over the mouth section of the mask could be entirely removed. But this should be done in the case of intelligent patients only, as then special attention has to be paid to the act of respiration. During sleep this valve, too, should always be in place."

The results of any new treatment in a pure pulmonary tuberculosis are always deceptive. The reason for this is to be found in the uncertainty of physical findings at different times of the examination and the psychical element of the patient which always enters in the appreciation of the value of any new therapeutic agent. We thought that it would be an interesting evidence of a therapeutic effect of Bier's treatment if we could apply Kuhn's mask after a careful examination of the throat, note the findings which the laryngoscope revealed, and then examine again the throat after the mask has been used for from 15 to 20 minutes.

The following are the results: Six cases of laryngeal tuberculosis were selected from the various wards in our service at the Riverside Sanatorium. On reexamination after the first application of the mask we were pleased to note that a marked congestion was produced in all the mucous membranes of the upper respiratory tract. This was especially noticeable in the membrane of the soft palate and epiglottis due to the usual pale character of the membrane in these parts. The anemic membrane, characteristic of such cases, was covered after treatment with a network of small dilated venulæ proving conclusively the utility of the mask to produce the desired venous hyperemia.

With this encouraging beginning the masks were worn fifteen minutes three times daily, and examinations made from time to time to discover any change in the pathological condition of the larynx. After a few days the congestion of the membranes became more or less permanent, lasting over from one treatment to another, the mucous membranes losing their characteristic pallor.

The cases ranged from the mildest with only slight infiltration of the cords and arytenoids with impairment of motion, to the severest type with extensive ulceration, and in one case perichondritis and external abscess.

During the application of the mask very little dis-

comfort was experienced by the patients, consisting of slight dizziness and feeling of oppression. This became less as the patients became accustomed to the treatment. In one case complicated with chronic otitis media with tinnitus, the dizziness became so severe as to interfere with the regularity of the treatment. This was especially true in heavy, stormy weather.

During the two months of treatment all the cases but one showed some improvement. In the cases of infiltration without ulceration the improvement was mainly symptomatic, the hoarseness and discomfort being relieved without any noticeable change in pathological lesion. Where ulceration existed the ulcers showed healthier, redder granulations covered by far less secretion than formerly.

The one exception to any improvement was the case spoken of with chronic otitis media and severe perichondritis. With him no relief was experienced that could be ascribed to the Kuhn mask.

During the first month all other local treatment of the larynx was suspended that we might not be doubtful as to the cause of any results obtained. Later, the eucalyptol, menthol, and chloroform inhalations referred to above were added with marked benefit to those cases suffering from irritable cough.

The present series of cases and the time of treatment have been too short to form a positive opinion as to its lasting value, but we have been able to demonstrate that the Kuhn mask is a practical means of applying the Bier treatment to the upper respiratory tract, and that under its influence local anemia has disappeared, symptoms improved and ulceration taken on a more healthy character.

This meager report does not mean, of course, that any cure has been discovered. Our only aim in making a preliminary report of these clinical experiments is to call your attention to one more of the means we have at our disposal to give relief in an affliction which must be considered as perhaps the most painful which the human flesh is heir to.

Let us hope that with the aid of the earliest possible diagnosis, proper hygiene, timely general sanatorium treatment in special institutions or at home, the utilization of all that has proved to be good in the line of local treatment, be it old or be it of recent date, and the judicious application of this Bier-Kuhn method, we may be able still more to diminish the horrible sufferings of our laryngeal tuberculous patients, and where we can not cure we may at least render the patient free from pain, make him comfortable, and prolong his life.

URTICARIA.*

By EDWARD B. FINCH, M.D.,
NEW YORK.

By urticaria we understand a disease chiefly affecting the skin and especially characterized by the production of certain peculiar lesions known as wheals. The production of wheals, or urtication as it has been called, occurs either artificially as the result of contact or penetration of the skin with certain irritants, such as the nettle or the hair of certain caterpillars, and the bites or stings of various insects, as well as spontaneously through certain derangements of the cutaneous economy. In both instances the lesion is practically the same, viz., the wheals. This essential feature consists of a circumscribed elevation which at its fully developed stage exhibits a striking pallor or waxy whiteness, without other change of the surface, and is invariably accompanied with intense itching. In most cases the process is a comparatively evanescent one, developing rather suddenly, beginning with an erythema, from the surface of which, after a short lapse of time, arises the wheal. Of the mechanism of its production our knowledge is somewhat vague. We know that there is a localized edema which accounts for the elevation, together with superficial ischemia. These conditions, together with the associated hyperemia, indicate some special process affecting the blood-vessels, and by inference also the cutaneous nerves.

It is the general opinion that both angiospasm and angioparesis have important roles to play in this connection. That a spastic condition constitutes an important factor in the process is partly evidenced by the behavior of the arrectores pilorum, which in most cases betray their violent contraction in the production of well-marked cutis anserina. This is especially well marked before the wheals have fully developed, and also in that form of urticaria known as dermographism. Here, perhaps, we may seek a plausible explanation of the symptoms of itching which the agitation of these little muscles might reasonably account for. (Bronson, "The Etiology of Itching." MEDICAL RECORD, Oct. 24, 1891.)

When urtication occurs spontaneously and becomes the disease urticaria, its cutaneous manifestations assume a variety of aspects and may be associated with a great variety of general conditions. All of these phenomena, as also those arising from external irritation, possess one characteristic in common. That is, there must be a peculiar susceptibility or predisposition on the part of the individual affected. What will cause urtication in one individual will not in another. In the urticarial subject the vasomotor nerves are in a condition such that any unusual irritation will cause a spasm of the vasoconstrictors. Whether underlying this there is a state of chronic toxemia, or whether a special toxin is produced at the time of an attack, we cannot say. In some cases it seems to be a pure neurosis, in others an autointoxication. Several years ago I saw a case where the exposure of the body to a cold draft of air or slapping the skin with a towel dipped in cold water was sufficient to cause an eruption of wheals. It is a common observation that certain persons are immune to the discomforts ordinarily felt from the bites of insects, and while the majority of people can partake of food stuffs and drugs with impunity as far as urticaria is concerned, there are others who can-

* Read before the Hospital Graduates Club, November 21, 1907.

not eat certain articles of food or take certain drugs without a very great probability of an attack of urticaria following the ingestion of these substances. I say probability, for the susceptibility of urticarial subjects to an outbreak varies in the individual, and what at one time may cause an attack of urticaria, may at others give rise to no untoward effects at all. While this is doubtless more or less true of the acute toxic variety of the disease, it is more especially so in the recurrent or so-called chronic form of urticaria.

The emotional or psychic causes of urticaria, such as grief, fright, or fatigue, usually act by their inhibitory effect on the process of digestion, and the patient evidently suffers from the same toxemia that the ingestion of certain foodstuffs may give rise to. But in one case of chronic urticaria, I have witnessed a slight outbreak, following an outburst of grief and indignation late at night, several hours after the ingestion of food and some time after the process of digestion must have been completed. Here it would seem that this patient was in a state of chronic toxemia and only needed some nervous irritation to precipitate an attack.

No specifically pathological condition of the blood has been observed in urticarial subjects, and the only pathological condition of the urine noted is a great excess of indican following the attack.

Itching and the forming of wheals are the constant symptoms of urticaria. The wheals may be few and scattered, or be extremely numerous and coalesce, forming large edematous masses. In one case I have observed an eruption so violent that within twenty minutes after the appearance of the first erythematous spot, the edema of the entire surface was so great, not only of the trunk and limbs but of the neck and head, that the patient looked as if roughly cast in wax. There may be gastric and abdominal pain, nausea, vomiting, and purging. Sometimes there is agonizing pain in the presternal region. Faintness going on to syncope accompanies some attacks, and is especially apt to follow the vomiting. When vomiting or fainting occurs, the eruption promptly disappears and the attack usually abruptly terminates. In the severe cases there may be an edema of the membranes of the nose, mouth, throat, and larynx, and the appalling symptom of suffocation may supervene. In angioneurotic edema, which is certainly closely allied to urticaria, a few fatal terminations from the involvement of the larynx and glottis have been recorded. I can find no such record for urticaria proper. In one case that I have seen, the edema of the glottis came on very suddenly, the patient struggled for breath for a few moments, and then became unconscious. But the moment the patient lost consciousness, the lesions on the skin disappeared, and with them the edema of the glottis subsided, and the patient was soon breathing naturally again, although hoarse for some hours after. 1/100 grain of nitroglycerin given hypodermically about 10 minutes before the patient became unconscious, may have had something to do with the favorable outcome, but my impression is that the syncope had more to do with the disappearance of the edema than had the nitroglycerine.

The same thing was observed in this patient during another attack by another physician, but at that time the patient did not become wholly unconscious, the edema disappearing with the relaxation due to vomiting.

In considering the treatment of urticaria certain ideas are suggested to us by a study of the pathology and by its symptomatology and course, especially of those cases of an acute, fulminating character. As we have already seen in these cases there is a spastic condition of the peripheral nerves and blood-vessels, probably due to a toxemia caused by the action of some irritant on the digestive organs. This is followed by the production of wheals and pains resembling those of angina pectoris. If a condition of syncope supervenes, the symptoms due to the angiospasm disappear. If vomiting and purging take place, there is not only a relief of the spastic condition, but more or less of the toxin is eliminated and the seat of the production of the toxin, the alimentary tract, is cleared out and the attack usually comes to an end.

The most useful drug I have found in combating urticaria, is creosote. Why its action is superior to that of the other antiseptics of the aromatic series, or of the so-called intestinal antiseptics, I am unable to state. It may be due to its greater volatility and therefore penetrability than the other members of this group, causing it to enter into less stable combination with proteid. As an intestinal antiseptic, as we understand the term, creosote does not rank high, so its action seems to be specific in regard to the special toxin which is the direct cause of urticaria when it is the expression of some internal disorder. Repeatedly have I seen cases of urticaria which had resisted the well-known methods of treatment clear up completely after the exhibition of a few doses of creosote. One case in particular I have in mind, that of a young lady who had had repeated attacks of urticaria hæmorrhagica extending over several years. She had run the gamut of most of the tried remedies and was thoroughly discouraged. During one of the attacks I put her on small repeated doses of creosote, and in two days all signs of urticaria had disappeared except the staining of the skin at the site of the hemorrhagic wheals. The creosote was continued after meals for eight or ten days longer and then discontinued; and for the two years following, while the patient was under my observation, there was no return of urticaria.

In acute toxic cases, if they be seen early, before the eruption is fully developed, the administration of creosote may greatly modify or even abort an attack. Four minims in elastic capsules with 2 minims in enteric pill should be given for an initial dose, followed every 15 or 20 minutes with 2 minims in capsule until an effect is produced.

In the recurrent or chronic forms of urticaria creosote may lessen the frequency of attacks or cause them to cease entirely as in the case cited. In this condition I have been in the habit of giving it after each meal and before retiring, from 2 to 4 minims in elastic capsule and 4 minims in enteric pill. One case that I have had under observation for some nine years has been pursuing this course for the past five years, varying the dose slightly and omitting it after meals for different periods, and whereas before beginning the creosote the attacks were of alarming frequency, now the patient will sometimes go for weeks or months without an outbreak. Failures, of course, are met with, just as in the treatment of malaria with quinine or rheumatism with the salicylates. In these cases salicylate of sodium is often valuable, its action as an antiseptic being less than that of creosote, but as has been shown by plethysmographic measurements the vessels of the skin are dilated, probably due to an excitation of the vasodilator centers in the medulla (Cushny), and its favorable action may be explained on this ground.

Salol is very useful, being decomposed in the in-

testine into salicylic and carbolic acids, and I have found it a valuable succedaneum to creosote in a stubborn case of urticaria (the last one mentioned), given in 5-grain doses with 5 minims of castor oil in capsule after each meal.

Frequently in violent outbreaks of urticaria, we must act quickly and energetically to relieve the symptoms, and our resources may be tried to the utmost. In a number of such attacks I have seen an emetic give prompt relief. Turpeth mineral, 5 grains, mixed in a little water, acted most satisfactorily. In the relaxation accompanying the act of vomiting, the bowels usually acted and then the purpose of clearing out the alimentary tract was fully accomplished. In one case, not having an emetic to hand, I gave a high rectal enema with gratifying results, the evacuation of the bowels being accompanied by vomiting and a fairly prompt subsidence of the edema.

When emesis fails to relieve the condition, or when it is contraindicated from any cause, recourse must be had to drugs which act as antispasmodics and vascular dilators. Atropine and nitroglycerin are the most useful for this purpose. Atropine has been recommended, to be given hypodermically, beginning with 1/150 of a grain and increasing the amount cautiously. My own experience has been that it is better to give one large dose 4/150 of a grain hypodermically, and I have had extremely good results in giving it in this amount. The dose has not had to be repeated, and it has been followed by a prompt subsidence of the symptoms. Only once have I seen any untoward results follow the administration of this amount of atropine, and then it was limited to a mild delirium which lasted for not more than half an hour. Nitroglycerin, 1/100 of a grain given hypodermically, will often act promptly, and the dose may be frequently repeated with safety.

Amyl nitrite, by inhalation, is especially valuable in those cases where there is much edema about the face and neck. It is peculiar in its action, relieving the spasms only in the head, neck, and upper part of the chest, and with its administration I have seen the eruption over those areas disappear as if by magic. It should prove extremely useful in those distressing cases where there is an edema of the tongue, pharynx, or glottis. In this condition a most useful adjunct to treatment is adrenalin chloride. This applied to the mucous membrane of the lips will cause the edema to subside promptly, showing that with the recurrence of edema the spastic condition in that particular locality has ceased. I have used it in an atomizer where there was an edema of the membranes of the nose, and of the tongue and pharynx, and its quick action in reducing the edema of these parts has been almost magical.

On the theory that the eruption might be controlled by the administration of the suprarenal gland substance itself, I administered it in two cases during an attack. It had absolutely no effect on the eruption, but in both cases caused a most agonizing abdominal pain, and in one of these cases, when it was given between attacks, the same abdominal pain followed its administration, succeeded by a violent outburst of urticaria. This untoward effect was probably due to the adrenalin increasing to a marked degree, a pre-existing spastic condition of the vasomotors.

The inhalation of chloroform, to the degree when it would cause general relaxation, has been suggested as an ideal way of aborting or relieving an attack, but circulatory failure has at times seemed so imminent I have not had the courage to give it a trial.

Itching, which is such a distressing concomitant to urticaria, frequently demands relief. For this purpose dilute vinegar, and lotions containing carbolic acid, resorcin, or thymol are useful. One of the most effective applications I have used is composed of chloral, camphor, and chloroform of each one dram in alcohol to make one ounce.

Menthol can seldom be borne, owing to the sensation of cold it produces. With warm alkaline baths I have had no success, perhaps owing to the fact that sufficient care was not taken to protect the patient from chill after the bath.

It is hardly necessary to add that in treating a case of urticaria the cause of the disease, both direct and remote, should be sought for and removed if possible, or any depraved state of the system corrected.

CYSTITIS IN WOMEN.

WITH REPORT OF FORTY-FIVE CASES, STUDIED CYSTOSCOPICALLY AND SOME MODIFICATIONS OF TREATMENT.

By ELLICE McDONALD, M.D.,

NEW YORK.

INSTRUCTOR IN OBSTETRICS, COLLEGE OF PHYSICIANS AND SURGEONS; CLINICAL ASSISTANT IN OBSTETRICS, VANDERBILT CLINIC; INSTRUCTOR IN OBSTETRICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

THE modern treatment of cystitis is the product of recent years; its development has depended upon the improvement in the structure of the cystoscope and the increase in skill and knowledge of its use. Before the interior of the bladder could be inspected and the pathological lesion observed, treatment of such conditions had to be, of necessity, empirical and indefinite. But with modern methods of diagnosis, direct inspection of the site of inflammation and visual knowledge of the effects of treatment, it is possible to control and to cure affections of the bladder in a direct and efficient manner. The ease with which the bladder may be inspected and the small amount of harm and discomfort of the cystoscopic examination in skilled hands are potent factors in the diagnosis, treatment, and cure of cystitis in women. It is thus possible to make an exact diagnosis of the bladder lesion, and appropriate treatment may be directed towards it.

If, however, no cystoscopic examination is made in cases of cystitis, it is impossible to localize the site of inflammation, acquire any knowledge of its size and location, or eliminate grave and dangerous affections of the kidney and adjacent organs. Many bladder and kidney lesions may produce mild symptoms, yet be of such a momentous character as to make their early diagnosis a necessity for the welfare of the patient.

It is possible with the cystoscope to detect the presence of inflammation by the appearance of the bladder; ulcers and tumors of the bladder wall are readily seen and treated, and the source of blood in the urine, that most important symptom in genito-urinary conditions, may be definitely located and appropriately treated. An intelligent prognosis cannot be reached without a definite diagnosis of the bladder and kidney condition, and this cannot be done without visual inspection of the bladder wall and the ureteral orifices; it is often necessary in addition to catheterize the ureters and obtain urine from each kidney for examination. None of

the newer methods of urine examinations, as cryoscopy, estimation of functional capacity of the kidney by methylene blue, etc., can take the place of ureteral catheterization in the study of surgical lesions of the kidney, as none of them is exact and accurate. The instruments for segregation of the urine by means of the formation of an artificial partition in the bladder, as by Luys'[1] segregator, or by means of pressure upon the ureters through the abdominal wall as by Heusner's[2] separator, are not to be depended upon for accurate division of the urines from the kidney, and have the additional fault that the resultant urine may suffer contamination from the bladder wall.

The cause and progress of the bladder disease and the effect of treatment upon the condition may be minutely followed by the cystoscope. Treatment may be changed to suit conditions that may arise and harmful procedures may be eliminated.

The ease and painlessness of cystoscopic examination eliminates the main argument against its use. In none of the following forty-five cases of bladder disease was the urethra or bladder cocainized. This includes several hundred examinations, as it was the custom to note the bladder condition cystoscopically at each treatment. In several cases, on account of the painful character of the lesion and the marked alteration in the bladder wall, opium suppositories were required to control the pains following bladder distention with the irrigating fluid. For inspection of the bladder with the examining cystoscope no dilatation of the urethra is necessary, save occasionally in virgins with a very small meatus. The instrument used for catheterization of the ureters occasionally requires slight dilatation of the urethra.

Cystoscopic examination should cause little or no pain, and no ill effects to the patient or to the patient's condition. No injury or ill effects from the examination alone were noted in any of these cases.

The instruments may be sterilized in formalin vapor or by scrubbing with tincture of green soap and placing in carbolic acid solutions. The ureteral catheters may be sterilized in formalin vapor or, as is the writer's custom, boiled in a saturated solution of common salt in water. Another useful solution for boiling catheters is saturated solution of ammonium sulphate in water; but this, while slightly prolonging the life of the catheters, causes crystals of the salt to be deposited on them during cooling. The common salt solution is convenient and efficient, one catheter of the writer having been boiled in this way eighteen times, before the silk and gum tissue became markedly injured.

The cystoscopic instruments used were a simple, indirect examining cystoscope of the Nitze type, the Tilden Brown catheterizing cystoscope, and the Kelly cystoscope as modified by Cullen. Other instruments were used experimentally, but the above were those constantly in use.

For diagnostic and catheterizing purposes water dilatation of the bladder was the rule. The patient was in the lithotomy position upon a gynecological examining table. If it was necessary to examine the bladder with the Kelly instrument for applications and other purposes, the hips were elevated, or the patient put into the knee-chest position, in order to get air inflation of the bladder.

The cases noted in this paper were all examined in a public clinic (Vanderbilt Clinic), and the fact that they returned for treatment is evidence of the lack of discomfort that the examination caused. The writer is indebted to Drs. Healy, Proben, Roff, Stone, and Meeker for referring these cases. The following abstracts of the histories of forty-five cases note the more important conditions found at cystoscopic examinations. The discussion of the cases follows their citation. Frequency of urination was the most common symptom which caused a cystoscopic examination to be made. This frequency in the histories is estimated in amount by the number of times a woman has to arise at night to urinate.

Clinic No. 44,529.—Frequency; pain; urgency. No return urgency. Right cystic ovary. Cystoscopic examination. Sclerotic stricture of the urethra. Chronic atrophic cystitis. Chronic hypertrophic trigonitis.

Clinic No. 46,270.—Frequency 3 to 4 times at night. Cystoscopic examination. Atrophic cystitis. Hyperemia of trigone. Diverticula of bladder.

Clinic No. 46,067.—Frequency 3-4. Cystoscopic examination. Calculous urethra. Loss of sphincter control. Acute hyperemic cystitis.

Clinic No. 43,833.—Frequency 1-2; pain; urgency. Symptoms date from operation of abdominal suspension for retroversion two years ago. Pain on left side. Cystoscopic examination. Bladder divided into two sacs by partition, which occupies the mid-line and corresponds to suspension ligament. Chronic hypertrophic trigonitis. Atrophic cystitis.

Clinic No. 44,995.—Frequency 3-5; pain; urgency. Uterus retroverted. Cystoscopic examination. Acute hyperemic trigonitis. Benefited by replacement of the uterus without further treatment and cured by bladder treatment.

Clinic No. 45,498.—Frequency; bearing-down pain; burning; urgency for two years. Left pyosalpinx. Endocervicitis and cervical enlargement. Cystoscopic examination. Acute purulent cystitis with marked hyperemia and edema of mucous membrane.

Clinic No. 45,500.—Frequency; burning and painful urination for three years, since birth of child. Frequency worse for last two months. Cystoscopic examination. Chronic hypertrophic trigonitis, with marked epithelial proliferation and definite reddening and localized inflammation of right ureteral orifice. Catheterization of kidney showed no tubercle in kidney urine.

Clinic No. 45,465.—Pain in back. Frequency for four years. No burning or urgency for last three years. Cystoscopic examination. Chronic atrophic trigonitis.

Clinic No. 45,499.—Pain in hypogastrium. Frequency 1-3; slight urgency. Left cystic ovary. Lactation atrophy of uterus. Endocervicitis and enlargement of cervix. Cystoscopic examination. Chronic atrophic cystitis. Chronic congestive trigonitis.

Clinic No. 45,379.—Slight. burning. Frequency 1-3. Marked frequency in day. Return urgency. Endocervicitis. and cervical enlargement. Cystoscopic examination. Chronic congestive cystitis. Chronic hyperemic trigonitis. Ureteral orifices normal.

Clinic No. 45,310.—Frequency, pain and urgency for six months. Has had frequency occasionally during last three years. Fibroma of cervix. Cystoscopic examination. Chronic atrophic cystitis, which is most marked where the cervical tumor bulges into the bladder. Acute hyperemic trigonitis. Both ureteral orifices inflamed and reddened. Catheterization of ureters showed kidney urine normal.

Clinic No. 43,919.—Frequency 2-4; urgency; moderate pain for six months. Bilateral salpingitis. Endocervicitis. Cystoscopic examination. Marked congestive hypertrophic cystitis. Large hypertrophied cervix uteri bulges into the bladder and keeps right ureteral orifice open.

Clinic No. 41,600.—Frequency and pain for one year. Blood in urine. Enlarged cervix, with endocervicitis. Cystoscopic examination. Chronic exfoliative cystitis in patches. Right ureteral orifice irritated and inflamed. Small ulcer undermined and serpiginous immediately above the orifice. Ureters catheterized, but no tubercle found in kidney urine.

Clinic No. 44,797.—Frequency, urgency, and pain for three years. Large uterus slightly prolapsed. Large cervix. Cystoscopic examination. Chronic hyperemic cystitis. Chronic exfoliative trigonitis.

Clinic No. 43,645.—Marked frequency, pain, and urgency for twenty years. Frequency often 10-20 times at night. Cystoscopic examination. Chronic hypertrophic cystitis. Marked chronic trigonitis.

Clinic No. 44,818.—Frequency and burning only when walking about. None at night. Cystoscopic examination. Marked urethritis. No inflammation in bladder save a little near outlet.

Clinic No. 44,862.—Slight frequency and pain on urination. Cystoscopic examination. Moderate atrophic cystitis. Upon left side are two ureteral orifices lying side by side, each of which extends to kidney, as methylene blue injected through one ureteral catheter flows out of the other.

Clinic No. 44,393.—Marked frequency, pain, urgency, and return urgency for two months. Bloody urine. Cystoscopic examination. Acute hyperemic cystitis, with bleeding granulations and a great deal of exfoliation. Ureteral orifices not inflamed more than the rest of the bladder. Ureter catheterized and kidney urine negative for tubercle.

Clinic No. 44,186.—Frequency 1-2 and slight urgency for four months. Right floating kidney. Perineorrhaphy four years ago. Moderate cystocele. Cystoscopic examination. Marked chronic trigonitis. Slight chronic cystitis. Right ureteral orifice reddened. Ureters catheterized and kidney urine negative for tubercle.

Clinic No. 43,700.—Age 19. Frequency 5-6. Urgency, pain, and return urgency for six months. Pain in right side for three weeks. Lost ten pounds in three weeks. Headache. No abdominal pain. Much pus in urine. Tubercle bacilli and long grooved angular leucocytes found in urine; their protoplasmic outline irregular and swollen. Vacuoles and detached nuclei in leucocytes. Many red corpuscles. Cystoscopic examination. Acute hyperemic exudative cystitis with several small ragged undermined ulcers. Right ureteral orifice markedly inflamed and left orifice slightly inflamed. Ureters catheterized. Tubercle bacilli, pus, and red cells found in right kidney urine, but left kidney urine clear. Nephrectomy by Dr. Blake showed right kidney with marked tuberculous disease. Bladder cleared up under treatment after operation. Patient gained forty pounds in six weeks following operation and was perfectly well in two months.

Clinic No. 45,672.—Age 23; three miscarriages. Frequency 2-3; urgency and pain for one year. Blood and pus in urine. Cystoscopic examination. Marked hyperemic cystitis with exfoliation and small ulcers with undermined edges around the right ureteral orifice. Right ureteral orifice markedly inflamed. Left ureteral orifice irregular, with some swelling and redness of the edges and slight congestion of the surrounding mucous membrane. There were a few reddish excrescences. Ureters were catheterized. Tubercle bacilli and pus found in the right kidney urine, and left kidney urine was clear. Nephrectomy refused. Bladder improved under treatment.

Clinic No. 46,343.—Age 16. Left tuberculous hip-joint disease with marked deformity. Frequency and pain on urination for three months. Cystoscopic examination. Moderate hyperemic cystitis with small, clear tuberculous-like fine gray points, surrounded by a reddish zone of congestion and inflammation. The whole mucosa is injected and swollen. Ureteral orifices are apparently normal. Pus and tubercle bacilli in urine. Ureters were catheterized and kidney urine from both sides was found to be without pus or tubercle; so it was concluded that the disease was primary in the genitourinary tract and was due to miliary extension from focus in the hip. The bladder condition improved somewhat under treatment.

Clinic No. 43,857.—Age 23. Hydatidiform mole three months ago. Acute gonococcus vulvitis and endocervicitis. Frequency, pain, and urgency for three months. Cystoscopic examination. Urethral hemorrhage, acute urethritis, acute hyperemic cystitis with bleeding granulations.

Clinic No. 44,146.—Pain, frequency, and burning for three months. Pelvis negative. Cystoscopic examination. Chronic exfoliative cystitis. Blood and pus in urine. Ulcer of the trigone with blood-vessel whose walls may be seen pulsating, running across the raw surface. Right ureteral orifice normal; left slightly reddened. Ureters catheterized. Kidney urine negative for tubercle bacilli.

Clinic No. 46,939.—Pain, frequency, and urgency for two months. Cystoscopic examination. Acute hyperemic cystitis with marked edema and much swelling of the mucosa.

Clinic No. 44,736.—Moderate frequency for eight months. Cystoscopic examination. Chronic atrophic cystitis.

Clinic No. 45,688.—Frequency and pain for six months. Pain on left side and back. Retroversion and endocervicitis. Cystoscopic hypertrophic trigonitis, with moderate edema and exfoliation.

Clinic No. 46,636.—Age 56; menopause at 37 years. Frequency 3-4; urgency and return urgency. Cystoscopic examination. Atrophic cystitis with hypertrophied bands of muscle and connective tissue and small diverticula.

Clinic No. 32,326.—Frequency, urgency, and return urgency. Perineorrhaphy and suspensio uteri three years ago. Cystoscopic examination. Chronic atrophic cystitis. Moderate hyperemic trigonitis. Bladder is distorted and ureteral orifices are displaced by fixed uterus.

Clinic No. 44,900.—Pain on urination and blood in urine for six months. History of syphilis. Pregnant four months. Cystoscopic examination. Marked hypertrophic cystitis with bleeding granulations. Large syphilitic (?) ulcer of fundus of bladder, marked varicosity of veins of bladder. False membrane of ulcer. Ureteral orifices negative. Ureters catheterized and kidney urine negative for tubercle. Bladder wall firm and cannot be distended. Improved under antisyphilitic and bladder treatment.

Clinic No. 44,370.—Frequency, burning, and pain for ten years. Bearing down pain. Cystoscopic examination. Chronic exfoliative cystitis with moderate papillary excrescences and small inflammatory cysts. Ureteral orifices patulous.

Clinic No. 43,735.—Frequency and pain on urination for six years. Operation for cystocele six years ago. Had electrical treatment, static and faradic, three years ago. Cystoscopic examination. Chronic hypertrophic trigonitis in the neighborhood of the scar of the cystocele operation, which can be seen as a ridge in the trigone. Right ureteral orifice inflamed and displaced as a result of the operation. Ureters catheterized and kidney urine negative.

Clinic No. 45,010.—Marked incontinence of retention and frequency for nine years, since complete hysterectomy nine years ago. Cystoscopic examination. Bladder markedly dilated with three large saculations. Chronic hypertrophic cystitis with very great hypertrophy of muscular and connective tissue bands, causing innumerable diverticula, 0.5 to 2.0 cm. deep. Much exfoliation of the mucosa and marked hyperemia. Ureteral orifices displaced, but otherwise negative. The bands of muscle resemble in appearance the columnæ cornæ of the heart valves.

Clinic No. 46,661.—Frequency, pain, and urgency for two years. Worse in last three months. Pregnancy three months. Cystoscopic examination. Severe granular hypertrophic cystitis over the whole bladder, with marked papillary granulations, which bleed easily. Marked exfoliation of mucosa. Ureteral orifices negative. Ureters catheterized, kidney urine negative for tubercle.

Clinic No. 43,815.—Burning and frequency for eighteen months. Worse since pregnancy began four months ago. Cystoscopic examination. Marked hyperemic cystitis. Mucosa soft and granular. Marked congestive magonitis.

Clinic No. 42,549.—Burning and frequency for two years. Worse since pregnancy in last four months. Chronic endocervicitis. Cystoscopic examination. Marked congestive trigonitis. Ureteral orifices patulous. Cervix bulges into the bladder.

Clinic No. 45,669.—Burning, pain, and slight urgency for three months. Pregnant three months. Cystoscopic examination. Moderate hyperemic trigonitis with congestion of vessels.

Clinic No. 43,821.—Burning and frequency for three months. Pregnant three months. History of pelvic peritonitis and cystitis two years ago. Cystoscopic examination. Chronic hyperemic cystitis with marked granular trigonitis.

Clinic No. 43,460.—Frequency for two months. Pregnant four months. Cystoscopic examination. Moderate hyperemic trigonitis. Ureteral orifice patulous.

Clinic No. 44,151.—Frequency, pain, and bearing down pain for two weeks. Pregnant three months. Cystoscopic examination. Marked congestive trigonitis; ureteral orifice normal.

Clinic No. 44,442.—Frequency, pain, and urgency for a week. Pregnant two months and a half. Cystoscopic examination. Slight hyperemic cystitis with papular trigonitis.

Clinic No. 42,622.—Frequency, urgency, and pain for three weeks. Pregnant four months. Cystoscopic examination. Moderate congestive trigonitis. Ureteral orifices dilated.

Clinic No. 45,051.—Frequency and pain for one month. Pregnant five months. Cystoscopic examination. Marked hyperemic trigonitis with papillary granulations and softening of the mucosa. Much exfoliation and desquamation.

Clinic No. 45,010.—Frequency and urgency for four months. Pregnant eight and a half months. Pain right side and much pus in urine. Cystoscopic examination. Marked purulent cystitis with papillary granulations, exfoliation, and desquamation. Marked hyperemia and edema of the mucosa. Ureteral orifices patulous. Ureters catheterized, and kidney urine contains no pus. Improved and went to full term under bladder treatment.

Clinic No. 44,688.—Frequency and urgency during last three months. Blood in urine. Pregnant nine months. Pain in abdomen under liver. Temperature 102°, pulse 110. Cystoscopic examination. Marked purulent cystitis with hemorrhagic papules and granulation-like spots. Marked varicose enlargement of the veins of the bladder,

hemorrhage from veins. Intense congestion, hyperemia, and edema. Much desquamation and exfoliation. Ureteral orifices patulous, but otherwise negative. Ureters catheterized and kidney urine contained no pus. Bladder improved under treatment and cleared up after delivery.

A short discussion into the pathology of cystitis will be required to explain these findings.

The most common condition of chronic inflammation of the trigone, or trigonitis, is usually one which results from a simple hyperemia and congestion of the vessels; actual infection may precede or follow the congestion. The line of separation between chronic congestion and chronic inflammation of the trigone is often hard to determine. There is usually marked hyperemia with marked dilatation of the blood-vessels. The intimate relation between the vesical arteries and those of the neighboring pelvic organs makes this very easy. The membrane loses its luster, the mucosa becomes reddened and there is evidence of flaky desquamation and exfoliation of epithelial cells, leucocytes, and pus. In a later stage, the mucosa of the trigone becomes velvety in appearance and, in some cases, there are proliferative processes, which may lead to papillary or papilloma-like excrescences. These cases of trigonitis show epithelial proliferation, marked round-celled infiltration, involving particularly the submucosa. In addition to these changes Heyman [3] has drawn attention to a change in the epithelial elements from the normal bladder mucosa to flattened epithelium. The epithelium is thickened and papillary projections may rise above the surface. These processes may take alveolar arrangement below the level of the surface.

In chronic cystitis, the changes are more general: the mucous membrane has lost its normal pinky white appearance, and appears more or less generally reddened. This reddening and inflammation may appear generally or only in certain patches, and cases have been noted in this series, in which the inflammation extended in streaks along the line of the blood-vessels of the bladder wall. The mucosa is dull red in appearance and may here and there show small ulcerations. There is frequently desquamation of the epithelium, and interstitial hemorrhages, showing on the surface, are not uncommon. When there is considerable ulceration and necrosis, membranous or gangrenous cystitis may result.

The muscle of the bladder is sometimes involved in the changes of cystitis and may hypertrophy and enlarge to project into the bladder cavity as thick bundles or network, forming cavities into which the bladder mucosa may penetrate. In one case, No. 45,010, this was associated with marked distention, lack of tone of the bladder wall and incontinence of retention. The muscular bands were as thick as a lead pencil and formed a network. The connective tissue in the muscle bundles increases and there follows a hypertrophic sclerosis of the muscle of the wall.

Chronic atrophic cystitis is not an uncommon condition in women after the menopause, and is often associated with more or less sclerosis of the external genitals, as in Case 44,529, where there was difficulty in urination on account of a sclerotic or atrophic vulvitis, and the white firm tissue around the external meatus constricted the opening to almost pin-point size; but was easily cured by one dilatation of the orifice with steel dilators.

The mucosa in atrophic cystitis is dull and thickened. The blood-vessels are not seen at the fundus and there is often atrophic retraction of the ureteral orifices. This process is usually accompanied by more or less irritating hypertrophic trigonitis. This condition is the most common cause of frequency of urination in women past the menopause.

Inflammation of the bladder is usually effected by congestion of adjacent organs. Thus an endocervicitis with enlargement of the cervix is not an infrequent accompaniment of a congestive hypertrophic trigonitis. The intimate relations of the cervix and the trigone and their blood-vessels explain this association. The enlarged cervix also often presses upon the trigone which from the existing inflammation has lost its normal elasticity, and this will often cause alteration in the structure of the ureteral orifices, which, from being small elevated papillæ, become stretched, flattened, and elongated. The base of the orifice may often be seen through the patent opening. This condition is also often present during pregnancy where the enlarged cervix bulges into the bladder.

These conditions injure the valve-like power of the ureteral orifice and causes it to allow of regurgitation of urine into the pelvis of the kidney. This may be a cause of pyonephrosis and pyelitis of pregnancy. This regurgitation was well demonstrated experimentally by Sampson,[4] who obtained it after injuring the ureteral orifices in animals.

Pregnancy, also from the congestion it brings, may be the cause of the recrudescence of an old trigonitis, as was noted in cases 46,661, 43,815, 42,549, 45,669, 43,821, 43,460, 44,151, 44,442, 42,622, and 45,051. In these cases there was in the early months of pregnancy some frequency and urgency of micturition. The increased congestion of the trigone showed very markedly in the engorged arteries, which could be traced upwards from the bladder orifice.

The writer also wishes to draw attention to a peculiarly acute cystitis in the latter months of pregnancy, which was present in two cases: Nos. 45,010 and 44,688. In these cases, both about full term of pregnancy, there was a very acute cystitis with large amounts of pus in the urine. Cystoscopic examination showed a very inflamed bladder wall with marked edema and hyperemia. The condition was general and uniform. There was marked desquamation and exfoliation of epithelium and pus. The exfoliated cells and shreds clung to the bladder wall like small tags. The picture was that of an extremely acute cystitis with very marked edema and congestion. The mucosa was markedly softened, swollen, and boggy. The amount of pus excreted was great.

In both of these cases examination was made on account of a suspected involvement of the kidney by pyelitis or pyonephrosis of pregnancy. In one there was pain on the right side, which seems to lend color to that diagnosis. However, catheterization of the ureters brought clear urine from the kidneys, eliminating all possibility of suppurating kidney conditions. These two cases gave such a clinical picture of pyelitis that it was only by cystoscopic examination and ureteral catheterization that such condition could be eliminated. The writer does not believe that a diagnosis of pyelitis or pyonephrosis of pregnancy, in the absence of marked renal tumor, can be definitely and accurately made without cystoscopic examination and ureteral catheterization. The place of origin of the pus in the urine must be definitely located. A purulent cystitis frequently accompanies infection of the kidney in pregnancy, and, without cystoscopic examination or the palpation of a marked renal tumor, it cannot be said whether the pus arises from the

kidney, the bladder, or both; the microscopical examination of the urine for renal or bladder cells offers no decided proof of either condition. An increase in temperature cannot be taken as a definite guide in the differential diagnosis of these conditions, as, in acute hyperemic cystitis of pregnancy, fever may be present as in case No. 44,688.

In the earlier months, pregnancy has a distinctly evil effect upon old or latent trigonitis. The added congestion of the blood-vessels and effect of the growing cervix bulging into the bladder causes an exacerbation of the condition. The diseased, inelastic trigone is stretched and irritated, and the ureteral openings are altered and distorted.

In one of the cases of pregnancy with cystitis, No. 44,688, there was marked hemorrhage from the bladder. This was due to markedly varicose veins in the bladder. The oozing could be directly traced to the enlarged vein, although it was also caused by the hemorrhagic granulations. Similar cases have been reported by Kubinyl,[5] who believes it to be due to the increase in blood pressure and the insufficiency of the valves of the veins. Proust[6] also reports two such cases in pregnancy, and they state that cystotomy, packing, and even direct ligation of the vein may be required. However, in this case, astringent treatment, while it did not entirely stop the bleeding, permitted the woman to go to term.

In three cases, Nos. 43,700, 45,672, and 46,343, there was tuberculous cystitis. In two cases it was associated with tuberculous disease of the kidney. One case was operated upon, the kidney remained and the cystitis cured; the other refused operation and the bladder was treated locally with small improvement.

The third case was one of tuberculous cystitis, primary in the genitourinary tract, but secondary to an old tuberculous hip-joint lesion. It is very rare in tuberculous genitourinary disease to find the bladder alone involved, as Saxtorph[7] in 10,016 autopsies found 205 cases of chronic genitourinary tuberculosis, and amongst these 205 cases there were 52 of secondary implication of the bladder and only one case in which the bladder was alone involved. However, in case No. 46,343 no other focus of tuberculosis could be found in the genitourinary system, and the extensive disease of the hip-joint did not seem to have been communicated to any other organ save the bladder. The uterus and tubes were free, the kidneys did not show any abnormality in urine and the lungs were not apparently involved.

The stage of invasion of the bladder in this case was the very earliest. The little gray white tubercles could be seen, surrounded by a reddish zone of inflammation, and in only two places did there seem to be any breaking down and ulceration. In these places the tubercles had apparently coalesced and formed a small conglomerate mass, which broke down to form an ulcer. The condition improved very slowly under treatment, and the patient is at the present time under observation. The condition of tuberculosis of the bladder is, however, most resistant to treatment, and a cure, except in cases where an involved kidney or other focus is removed, is rare.

Amongst the forty-five cases were four in which the bladder inflammation was the result of or followed upon a previously gynecological operation. Two cases followed suspension of the uterus by the abdominal route. In one case, there was marked sacculation of the bladder with patches of inflammation and congestion; in the other there was considerable distortion of the trigone, alteration in the site of the ureteral orifices, and sacculation of the bladder. In case No. 45,010 there has been a complete hysterectomy for purulent tubal disease. The bladder was very markedly dilated and would retain 1,500 c.c. The walls were much congested, and the fibers of bladder muscle were separated into a network of firm, stout bands, the largest as great as a lead pencil and the smallest as the lead itself. The mucous membrane dipped into the crevices and the ureteral orifices were much distorted. The bladder was very irregularly dilated and had lost its tone: incontinence of retention was present. This case improved somewhat under dilatation of the urethra and other treatment. Case No. 43,735 had had a cystocele operation, and the scar of the operation wound could be seen within the bladder, although it did not seem to have penetrated the bladder mucous membrane. The left ureteral orifice was displaced and the region of the scar inflamed and congested.

Bladder inflammation following upon gynecological operations is not infrequent and is usually blamed upon a postoperative cystitis; however, it frequently happens that the cause may be more directly laid to the operation itself as in these four cases.

Blood in the urine is said to be an indication of tuberculous genitourinary disease; but in this series it appeared several times when tubercle bacilli could not be demonstrated in the urine. It was due in some cases to a small bleeding ulcer and, in one case of acute cystitis of pregnancy, to bleeding granulations and varicose veins of the bladder. It is, however, a symptom which is a direct and urgent indication for accurate study of the case and visual diagnosis of the lesion by means of the cystoscope.

One case, No. 44,900, showed a large single ulceration of the fundus with marked necrosis and false membrane formation. The bladder was uniformly inflamed and markedly contracted. The case was watched and treated throughout pregnancy without benefit; but after delivery slight improvement took place under antisyphilitic treatment. Operation of cystotomy was refused. Curettage of the ulcer was not done on account of the friability of the bladder wall.

The treatment in general of these cases of cystitis consisted of irrigations with a bland cleansing fluid. This solution usually consisted of sodium bicarbonate, one dram to the quart of water. This is a better solvent of mucus, pus, and albuminous substances generally than is the boric acid solution so commonly used. This is well known by otologists, who recognized the value of alkaline solutions in suppurative ear diseases. If there was a great deal of mucus, the solution was made of double strength, and, if there was a great deal of pus, one dram of sodium sulphate was added to the cleansing solution. These mixtures are bland and cleansing, and offer some advantage over the common boric acid solution.

Various antiseptic solutions were tried in the hope of finding one which would give the maximum effect with the minimum amount of disturbance. Roysing's[8] carbolic acid solution, five per cent., was tried in the cases of tuberculosis of the bladder and in other chronic cases. It caused a great amount of pain, in one case hemoglobinuria, and did no good. It was tried in all in twelve cases, and only one case was benefited. A number were made worse symptomatically and their condition

was not improved. The treatment is one of great severity and often causes intense irritation.

Sublimate solutions were not tried, as the known inefficiency of this antiseptic in the presence of albuminous matter was considered a contraindication for its use. It has been used by Guyon,[9] but has not been praised by other surgeons.

In the search for an antiseptic astringent of comparatively unirritating properties, quinine was tried. This substance has distinct antiseptic properties and is said to be placed midway between bichloride of mercury and carbolic acid in its antiseptic properties. It is comparatively unirritating, easily obtained, and may be retained in the bladder without danger. The salt used was the bisulphate, which is easily soluble in water and was made up one dram to the pint. This solution had a distinctly good effect and was the most efficient of the antiseptic solutions used. The few cases reported here cannot be made the basis for the introduction of a new treatment; but the marked improvement in treatment of chronic cases by this solution was encouraging.

Various silver salts were tried and the nitrate was found to be so irritating that its use was discontinued. In the choice of the colloid silver preparations, the experience of chemists and ophthalmologists was considered. It has been found by Derby[10] that of these various preparations argyrol and collargol are inert as bactericides, and that all the colloid silver salts are inefficient in the presence of albuminous matter. The preparations may be divided into three classes: the non-irritating of low bactericidal power, as argyrol and collargol; the more effective and slightly irritating bactericides, as protargol; and the very irritating preparations like nitrate of silver.

It has also been shown by Marshall and Neave[11] that the percentage of silver in the compound is no criterion of its antiseptic value. For these reasons, and after some trial of several salts, it was concluded that it was better to have a preparation as protargol with some bactericidal power at the expense of its slightly irritating properties than one like argyrol, which has little or no bactericidal properties and is non-irritating. Protagol, 5 per cent., was by no means used as a routine treatment. It was used in chronic trigonitis for local applications to the inflamed part and as an injection in marked chronic cystitis.

In acute purulent cystitis with exfoliation and pus formation, it was used with hydrogen peroxide as a cleaning and antiseptic combination. It has been shown by Futh[12] that in the treatment of necrotic endometritis and suppurating wounds, if a colloid silver compound is used along with hydrogen peroxide, the action of each is made much more effective. For this reason the two were combined in the treatment of purulent cystitis. Hydrogen peroxide, one-third strength, and protargol, 5 per cent., were injected alternately through a catheter into the bladder by means of a half-ounce syringe. The mixture was allowed to act for a few minutes, then it was washed out by the cleansing solution, injected by the same syringe. No difficulty or trouble was ever noted from distention of the bladder by the peroxide. The peroxide foam poured out of the catheter and was finally washed out by the quinine solution or the cleansing solution. This treatment is not one which would be advised for cystitis in the male, but it has given excellent results in purulent cystitis in the female.

The exfoliation, desquamation, and pus cells are in this way washed away, as they cannot be by any irrigation; the bladder mucous membrane is left clean, and is prepared for treatment by antiseptic or astringent solutions or for direct applications.

For direct applications to ulcers and localized inflamed spots nitrate of silver fused on a metal probe, or protargol solution on a swab, was used. The patient was put in the knee-chest position, and applications were made through the Kelly-Cullen cystoscope. The place for the application was first located by means of the examining cystoscope under water dilatation.

It was also found that in cases of acute cystitis, or cases where there had been extensive treatment, a soothing application was of benefit. Olive oil was used with some success, but finally a preparation of Irish moss was found to be the most useful. The value of this preparation consists in keeping the bladder walls apart and lubricating them, so that no friction or irritation results. The preparation is approximately the same as many lubricating jellies put up in tubes for use in vaginal examination. This soothing lubricating preparation of Irish moss is also of use in lubricating the cystoscope before its introduction into the urethra. It is prepared as follows:

Chrondus (Irish moss)....45 g.
Distilled water.....1500 c.c.

Wash the Irish moss in cold water, drain off water; wash again and drain. To the washed Irish moss add 1,500 c.c. of distilled water and boil for ten to fifteen minutes, stirring frequently. Strain through muslin with expression. To the strained Irish moss add 4,500 c.c. of boiling distilled water and filter. The process of filtration may be hastened by loosely filling the filter with absorbent cotton. Evaporate the filtrate to one-fifth by bulk, cool partially and add gomonal, 1 per cent. by weight, mix well and strain through fine white flannel which has been previously boiled. Bottle in ground glass stoppered containers of about half a pint each.

This Irish moss jelly makes a useful lubricant for examinations and may be put up in sterilized metal paint tubes for that purpose. In bladder treatment the jelly should be diluted with hot water to a thick semisolid consistency, fit for use in a syringe.

The treatment of these cases of cystitis consisted mainly in the use of four compounds: the antiseptic quinine solution, the cleansing bicarbonate solution, the peroxide and silver combination, and the jelly of Irish moss. In addition to this, appropriate treatment was directed to ulcers by direct application of silver or curettage, as was required; chronic patches of inflammation were stimulated, and lesions in the neighboring organs were treated.

If the case was one of acute purulent bladder disease, the bladder was first inspected and a diagnosis made, the bicarbonate solution being used as the dilating fluid. The pus and shreds were then washed away by the peroxide and silver combination. The bladder was then washed and dilated by the quinine solution and more exact examination made for small ulcers, patches of inflammation, and the condition of the ureteral orifices. If it were necessary to catheterize the uterus, it was usually done under the quinine solution and after the bladder had been cleansed. It was believed that in this way danger of carrying infection upwards from the bladder was eliminated, the cleansed bladder wall and antiseptic quinine solution removing this small danger. The quinine solution gives a pecu-

liar bluish appearance through the cystoscope, but examinations can be well made with it.

If the case is one of very acute irritation, the Irish moss jelly is injected on removal of the quinine solution. The amount of jelly injected should vary from one to four ounces. If, however, the bladder inflammation is more chronic, the patient is told to retain the quinine solution as long as possible in order to get full benefit from its antiseptic and astringent action.

In chronic cases with much congestion and irritation the peroxide and silver combination was seldom used. The aim of the treatment in all cases was first to cleanse the infected area, to direct appropriate treatment toward the special lesion, and to exercise an antiseptic astringent and stimulating action upon the mucous membranes by means of the quinine solution.

It was also found useful to use various drugs by the mouth. Infusion of buchu and fluid extract of triticum are old favorites and have no equals for making the urine bland and unirritating. Tincture of belladonna and potassium or sodium bicarbonate should be used in combination to relieve spasm and make the urine alkaline. It is required in cases of cystitis that the urine be made alkaline during the irritating stage of the disease. Acid urine is always irritating. The patient should also be directed to drink large quantities of water and a specified amount of six glasses should be named in order that the directions be carried out.

The use of hexamethylene tetramine (urotropin) has not been satisfactory in the writer's experience. It is inert, save when the urine is acid and it makes the urine rather irritating. It is very irritating to the kidney and, when first given, acts as a diuretic; but on continued use may do harm. The writer wishes to sound a note of warning in regard to the prolonged use of this drug. Its value in purulent kidney conditions is undoubted; but it is of very little use in cystitis and the continued use may cause kidney irritation and hemorrhagic urine, as has been noted in four cases in the writer's somewhat limited experience. Many additional cases of the toxic effects of this drug have been collected by Beardsley.[13] Guaiacol is a useful and efficient substitute, but it is also seldom required in cystitis.

The therapeutic value of rest is very great in these cases, and a bland diet with avoidance of acid elements should be ordered. It is also important to remember that the occasion of a cystitis sometimes depends upon a coincident lesion and the bladder inflammation may not react to treatment until that is cured.

THE PHYSICAL SIGNS OF INCIPIENT PULMONARY TUBERCULOSIS.

By ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO.

In this communication, the writer intentionally ignores a review of the accepted signs peculiar to early phthisis with the object of giving prominence to a few original methods which he has successfully employed for many years in diagnosis. He can only refer succinctly to methods which he has already reported and is therefore constrained to direct the reader to the original communications bearing on the subjects cited. The successful treatment of pulmonary tuberculosis postulates an early diagnosis and justifies nearly always the aphorism: *Tuberculosis primis in stadiis semper curabilis.* One must not conclude the antithesis in later stages of the disease. Whereas one may diagnose early phthisis, one cannot always prognosticate, inasmuch as the character of the soil on which the seed has fallen is not always the object of correct interpretation, for considerable differences exist in the stock of vitality contributed to the body in different individuals. Thus, lung cavitation is, in my experience no index of an unfavorable prognosis, for such a condition is often an objective demonstration of tissue-resistance to germ invasion, very often a localized process and an available field for bronchial drainage. As a rule, the traditional aphorism, "*Qui bene diagnoscit, bene curat,*" applies most cogently to phthisis. Before one can properly appreciate the physical signs of early phthisis, one must possess a correct conception of the lung condition peculiar to this stage of the disease or antedating it.

The Lungs in Early Phthisis.—The essential morbid anatomy consists of a catarrhal process plus infiltration of the peribronchial and submucous tissues. The lungs predisposed to phthisis or already invaded show the presence of constant areas of diminished lung resonance varying from dullness to flatness as elicited by percussion. These areas or *atelectatic zones*,[1] as I have called them, may be dispelled by repeated forced inspirations or by vigorous cutaneous irritation so as to induce the *lung reflex*.[2] Not infrequently an entire apex may be collapsed or atelectatic and the condition may be interpreted erroneously either by percussion or radiodiagnosis[3] as an infiltration. However, repeated forced inspirations plus the lung reflex will eliminate any error in this regard. In individuals predisposed to tuberculosis and in those who already have the disease, the lungs are practically in an emphysematous condition,[4] viz., dilatation of the air vesicles with disappearance or loss of tone of the elastic fibers. The following conclusions have been formulated concerning this emphysematous lung condition or acute pulmonary dilatation:

In health, the percussion note of the lungs is resonant during inspiration, and dull or even flat during forced expiration.

2. In emphysema, the percussion note is unchanged during the two phases of respiration.

3. This unchanged percussion note, heretofore recognized in pulmonary vesicular emphysema is pathognomonic of lungs predisposed to tuberculosis, and of lungs already affected.

4. Associated with the unchanged percussion sound, there is an extension of the lung borders manifested by downward dislocation of the lung and diminution often to the extent of obliteration

of the cardiac, hepatic and splenic areas of absolute dullness.

5. Unchanged percussion resonance, hyperresonance, and prolongation of the expiration are indicative of deficient expiratory force of the pulmonary substance, and constitute the earliest trustworthy signs of the so-called pretuberculous stage of tuberculosis. The restricted diaphragmatic movements peculiar to early phthisis owe their origin to the emphysematous lung condition.[5] Rokitansky noted that too voluminous lungs coupled with a small heart characterized the phthisical habitus. This observation was soon relegated to oblivion, but it was revived by Brehmer and vigorously defended. The too voluminous lungs of Rokitansky and Brehmer are practically the lungs of emphysema (acute pulmonary dilatation).

I may be permitted to swerve from the continuity of my subject for the purpose of considering the relation that the lung condition in early phthisis bears to the treatment of the disease. It is not so much a question of how much air enters the lung as it is of how much air gets out. The stagnant pools of residual air promote a state of tissue asphyxiation, the patient practically rebreathing the air.

Some years ago[6] I demonstrated clinically that the vagus nerve contained bronchoconstrictor and bronchodilator fibers, and this observation was conclusively established later by the experimental investigations of Dixon and Brodie.[7] The writer has availed himself of the latter fact, and by inducing the lung reflex of contraction[8] in the treatment of phthisis, emphysema, and asthma, one may wield a puissant force in antagonizing pulmonary conditions associated with dilatation of the lungs.

Pulmonary Anemia.—Many years ago[9] I directed attention to the occurrence of anemia of pulmonary origin associated with atelectatic zones and dependent on insufficient lung development. This form of anemia is characterized by loss in weight, whereas in the essential anemias, the well nourished condition of the patient is manifest.

There is another sign which distinguishes pulmonary from other forms of anemia, the one exception being, perhaps, progressive pernicious anemia, and that is the fact that, while the ferruginous preparations benefit pure anemics, in pulmonary anemia, they are practically valueless, at any rate the benefit accruing from their use is evanescent. The real pathognomonic sign of pulmonary anemia is the therapeutic test. Subject such an individual to a single pneumatic cabinet treatment, employing inhalations of compressed air, and one invariably finds after an examination of the blood an increase in the percentage of hemoglobin. A collective investigation demonstrated that the hemoglobin percentage could be increased, on an average, 15 per cent., after a single séance in the pneumatic cabinet. In the absence of a cabinet, a series of forced inspirations and expirations are less effective, although nevertheless efficient in establishing an augmentation in the percentage of hemoglobin. Pulmonary anemia is likewise one of the most important symptoms of early phthisis and may precede all other recognizable signs.

The reader is referred elsewhere[10] for the explanation of the therapeutic test in pulmonary anemia. The writer is cognizant of the fact that the hematologist does not concede the existence of anemia in tuberculosis although practically every clinical symptom negatives the latter observation. The writer recognizes that the condition of the blood prevailing in polycythemia bears some relation to the condition which exists in tuberculosis. In polycythemia, dependent on chronic venous stasis, the capillary blood owing to its concentration contains more red corpuscles and hemoglobin than normal, and it is assumed that while this condition may exist in the peripheral circulation, it is not necessarily so with the blood in the rest of the body. This polycythemia is explained by supposing that owing to deficient oxidation, the result of the stasis, an augmentation of red corpuscles occurs as a compensatory process.

Vibrosuppression.—I have very recently described[11] an instrument called the vibrosuppressor for restricting vibrations of the sternum. In the absence of the latter simple apparatus, the lower end of the sternum may be forcibly compressed by the hand of the patient or an assistant while percussion is executed by the physician. If in association with compression of the sterum, percussion is executed during suspension of breathing after the patient has practised forcible expiration, the organs may be outlined with marvelous accuracy. This method, however, is especially available in the recognition of dullness peculiar to early phthisis. In the latter affection, resonance (owing to dilatation of the lungs) is the usual phenomenon elicited by percussion, but if vibrosuppression is employed, dullness of one or both apices may be recognized. The writer has much reason to emphasize the importance of the latter sign.

Auscultatory Percussion.—If, during percussion, a stethoscope is allowed to hang from the ears of the physician (no part of the instrument being in contact with the chest of the patient), nuances in the percussion sound, unrecognizable by unassisted audition, are demonstrable. Here the stethoscope is employed as a microphone, and the writer has also found this simple expedient of value in topographic percussion. The writer's modified method of auscultatory percussion[12] is available in the elicitation of lung consolidation. It embodies the principle of transsonance. If it is desired to elicit the transsonance of the apices, the stethoscope is fixed first over one and then over the other apex, while immediate percussion with the finger is executed over a prominent vertebra. If the apices are to be auscultated posteriorly, the percussion blow is limited to the manubrium sterni. By this maneuver, one may easily recognize departures from normal transsonance provided the physician has familiarized himself with the latter, which is not difficult of attainment.

Auscultation.—Owing to the respiratory immobility of the lung apices, many auscultatory phenomena may escape recognition, and it is therefore often imperative to augment the respiratory activity of the apices. The latter object may be achieved by binding the lower chest prior to auscultation with a rubber bandage.

Tracheal Traction Test.—I have described this test[13] as an aid in the diagnosis of idiopathic asthma. When the head of the patient is thrown forcibly backward or turned to one side and so maintained during percussion, the normal resonance obtained by percussion over the manubrium sterni and lungs contiguous thereto becomes translated into a dull or flat sound during the time the cervical muscles are contracted. The latter evoke contraction of the bronchial muscles by stimulation of the pneumogastric nerves. The maneuver in question by contracting the bronchial tree will accentuate râles or other acoustic phenomena which may be present

either over the apices or elsewhere over the lungs.

Stethophonometry.—If one is in the possession of a stethophonometer,[14] one may estimate the comparative intensity of the sounds heard over both apices. Assuming that no stethophonometer is at our command, then the latter may be improvised by using the ordinary binaural stethoscope with soft rubber attachments. If, *e.g.* with one rubber tube compressed by the finger, the apical respiratory murmur is barely audible over one apex and very loud over the other apex, it is evident that the murmur is exaggerated in the latter situation.

Tuning Fork.—The writer regards the tuning fork of some value in testing the conductivity of the lung tissue and employs it after the following manner: A fork (with 120 vibrations) is attached to a cork and the latter is grasped by the teeth of the patient. Forks may be purchased with a hard rubber attachment, rendering the employment of the cork unnecessary. Without removing the tuning fork from the patient's mouth, the prongs are made to vibrate by compression by the fingers of the physician, during which time the apices or other portions of the lungs may be auscultated. The situation of the bronchi is revealed by the exaggerated transmitted hum, and the hum is equally modified by the normal and consolidated lung.

CARCINOMA OF THE RIGHT NASAL CAVITY AND OF THE ANTRUM OF HIGHMORE.*

By LOUIS KLEMPTNER, M.D.,
SEATTLE, WASH.

Rosa D., 33 years old, consulted me on July 20, 1907. She complained of headaches, an increasing obstruction of the nose for the last two years, an increasing swelling of the right side of the face and of the right eyelids for the last three months; she had been losing flesh lately and was getting pale; she was never sick before.

The patient is thin and pale; the internal organs are normal; no symptoms of lues. The right cheek and the right lower eyelid are swollen; the right eye is much smaller than the left. In translumination the right antrum of Highmore is much darker than the left. The whole nasal cavity is filled with a growth, which is visible by lifting the tip of the nose. This growth, the surface of which is irregular, has displaced the septum to the left and partly filled the nasopharynx. There is a scant odorless mucous discharge from the nose.

The microscopical examination of a piece of the growth removed for the purpose of diagnosis revealed a malignant tumor, apparently carcinoma.

The patient was operated upon by me at the Yorkville Hospital on July 25, 1907, according to Denker's method, a detailed description of which can be found in the *Münchener medizinische Wochenschrift*, No. 20, 1906. I made a horizontal incision in the mucous membrane of the anterior wall of the right superior maxilla, beginning half an inch to the left of the frenum above the sockets of the teeth, and enlarged the incision upwards to the apertura pyriformis and outwards to the last tooth. It became evident that destruction had already taken place of the periosteum and bony wall in the fossa canina, the size of a quarter of a dollar, through which opening the tumor was bulging. The soft parts were pushed back upwards to the lowest margin of the orbit and inwards, until the lateral and lower margins of the apertura pyriformis were laid open. The whole anterior wall of the antrum and the growth which filled it were then removed. The interior wall of the antrum was also in great part destroyed by the tumor in the region of the middle turbinated bone. I separated the mucous membrane of the lateral nasal wall from the bone below the inferior turbinated, and removed the whole interior bony wall of the antrum from the apertura pyriformis, as well as the inferior turbinated. Then followed the resection of the middle turbinated, the removal of the tumor masses from the nasal cavity and the nasopharynx, the removal of all the ethmoidal cells, which were almost destroyed by the growth. The frontal and sphenoidal cavities were not affected.

The loosened mucous membrane of the lateral wall of the nasal cavity was used to cover the floor of the antrum, and the so formed single big cavity was filled with iodoform gauze. The wound of the mouth was then closed. The after treatment was carried out through the nose. The course after the operation was very satisfactory. The highest temperature was 101°, on the third day. On the fourth day I removed the packing and did not renew it; on the sixth day the sutures were removed; the wound of the mouth healed *per primam*. After 10 days the patient left the hospital. I cleaned the

Fig. 1.—Alveolar carcinoma with cyst formation; stroma consisting of connective and granular tissue.

*Paper read and patient presented before the Clinical Society of the Yorkville Hospital, New York City, October 17, 1907.

wound the first two weeks, and then the patient syringed it herself with a boric acid solution. There was little secretion or formation of scabs.

Now, four months after the operation the swelling of the face has disappeared; the right eye is as large as the left. The nasal cavity and the antrum of Highmore form one large cavity, the walls of which are smooth; the septum is straight; looking upwards and backwards one sees the opening to the sphenoidal cavity. There is no sign of recurrence. The patient feels very well and has gained in weight.

Dr. Israel Strauss made a microscopical examination of the growth and diagnosed it carcinoma originating from the mucous glands. The specimen presents a stroma consisting partly of connective tissue, partly of granular tissue, in which are irregularly disseminated alveoli filled with masses of epithelial cells. The alveoli are different in form and size, round or elongated, and sharply defined from the surrounding stroma, which forms the walls of the alveoli. The masses of the epithelial cells are partly compact and partly contain irregularly formed cysts of varying size surrounded by layers of those

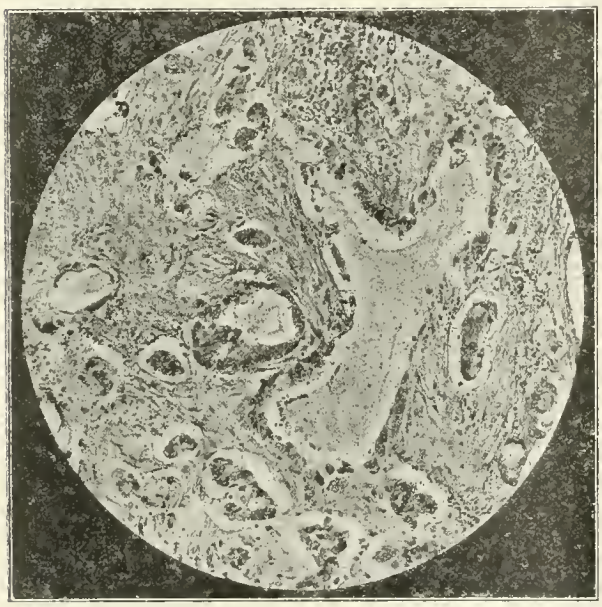

Fig. 2.—Enlarged photomicrograph showing polymorphous cells, many of them possessing several nuclei.

cells of varying thickness. The interior of the cysts is filled with a homogeneous mass. The cysts apparently present more or less advanced phases of destruction of the cells. The cells are polymorphous, many of them possess several nuclei, which are well stained.

The great destruction of the walls of the antrum and of the ethmoidal cells pointed to malignancy of the growth. The microscopical examination proved the growth to be carcinoma. The case is interesting on account of the relative youth of the patient, the absence of a recurrence, and the absence of any deformity despite the removal of such large bony masses.

The operation in this case is only a further development of the radical operation for empyema of the antrum of Highmore, as elaborated by Caldwell, Boeninghaus, Kretschmann, Friederich, and Denker. This operation has the great advantage over other operations for malignant growths of this region in that there is no disfigurement of the face, the process of healing is much shorter in duration and less tormenting, and the after-treatment is simple and soon easily managed by the patient himself. The result speaks for itself.

The photomicrographs in this case were made by Dr. Leopold Jaches of Cornell University Medical College.

SUDDEN DEATH IN PNEUMONIA,

ITS CAUSE AND PROPHYLAXIS.

By W. PARKER WORSTER, A.M., M.D.,

NEW YORK.

Patients dying in pneumonia do not die from feebleness of the heart, as many suppose. Enfeeblement of the heart has nothing to do with it; that is less the cause of death than another more important factor which in such cases is at work.

Collapse of the capillary blood-vessels due to a paretic condition of their walls, or a condition of stasis in which the walls remain distended and flattened out, is the real cause of sudden death in pneumonia. The vessels have lost their resistance and that elasticity which propels the blood through them and that loss of elasticity is the result of the toxemia poisoning the nerve centers in the medulla. Those centers are paralyzed and consequently the coats of the arteries and veins are also paralyzed, rendering them useless and forming a permanent obstruction to the flow of blood back to the heart.

In the last stages of pneumonia, when the temperature is down, when the lungs are clogged with hypostatic congestion, when the dyspnea is excessive, respiration shallow and frequent, and the heart is laboring to compensate for the loss of elasticity in the peripheral vessels which is so essential to normal conditions, if they can be freed so as to allow the patient to breathe freely, the whole aspect of the case will change for the better and the patient will recover. Therefore the chief indication is to remove that obstruction and do it quickly, or the patient will die suddenly. The excitation of cold is the most powerful and energetic agent for combating such collapse and can be accomplished in the following manner: A bathtub of water at 100° to extend just above the patient's hips is prepared and the patient placed in it or held in a semi-recumbent position, and several basins of water at 60° or lower, as the case may indicate, are poured over his shoulders, chest, and back, the operator standing on a chair and holding the water as high as possible so as to get the required force.

Such a procedure, if the patient is unconscious or delirious, low muttering or otherwise, will often arouse him to consciousness and brighten his eye and his countenance will wake up from its apathetic appearance, his shallow respiration will become deeper and the excitation of the cold upon his bronchial tubes will cause him to cough and expectorate and free them from mucus and his air-cells from threatened hypostasis, his cyanosed and marble skin will become ruddier, the capillary circulation will be reestablished, and the heart will gain in force and diminish in frequency.

This procedure will positively change the whole aspect of the case and perhaps only one application will suffice to save the life of that patient, as I can testify from personal experience and practical bedside results.

I wish to warn against the fear of a cold application given in the manner described above in such conditions, as the refreshing, stimulating, and life-saving effect of such will never be forgotten by any one who has once witnessed it.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 22, 1908.

DIAGNOSIS OF THE LOCATION OF THE APPENDIX IN ACUTE APPENDICITIS.

THE appendix usually lies behind and to the inner side of the cecum. Its location varies, however, both because the cecum does not occupy a fixed position in the abdomen and because the origin of the appendix in the cecum may be variously placed. In the *Deutsche Zeitschrift für Chirurgie* (Volume 91, No. 1) Krüger describes how the location of the appendix may be ascertained before operation, he having made a correct diagnosis in 375 cases. He assumes that all the possible symptoms which an acutely inflamed appendix can cause are not present in every case, but that certain symptoms are present in one case and absent in another. This variance in symptoms is due to the different pathological changes possible in the appendix and its surroundings. The pathological changes, on the other hand, depend partly upon the location of the appendix. From these premises Krüger concludes that the symptoms vary with the location of the appendix, and therefore the former aid us in diagnosing the position of the latter.

Vomiting usually sets in only when the serosa of the appendix has become involved and when there has been an irritation of the peritoneum of the general abdominal cavity. The number of times a patient vomits depends upon the area of inflamed appendicular serosa coming into contact with the general abdominal peritoneum and upon the virulence of the infection. Therefore, if there is a great deal of vomiting the appendix probably lies free in the abdominal cavity, while if there is little or none, it lies imbedded in adhesions, or lies behind the cecum and ascending colon. Distention, which is caused by the involvement of some other portion of the intestine, is rare in the earlier stages, and when it does occur early it is a sign that the appendix lies towards the general abdominal cavity or in the true pelvis, where it is most likely to come in contact with loops of intestine. Absence of early distention is in favor of a retrocolic appendix. Bladder symptoms point to the appendix lying in the true pelvis. Muscle spasm is also of value in diagnosing the location of the appendix. When the inflammation has extended by continuity from the serosa to the abdominal wall, the parietal peritoneum and muscle become involved, causing a circumscribed resistance of the wall. The latter is due to contractions of the rectus muscles, brought about either reflexly or by inflammatory irritation. This spasm is present early when the appendix lies in front, but we rarely see it early when the appendix lies behind. Pain on moving the hip joint, or the fact that a patient constantly holds the thigh flexed, is a sign of ileopsoas spasm, from which Krüger concludes that the appendix is in immediate relation to that muscle. Pain at the free border of the ribs on deep inspiration points to the appendix lying in the upper portion of the abdomen; if there is in addition spasm of the rectus, it lies in front; if there is pain in the lumbar region, it is retrocolic, the latter position being the more frequent. Krüger admits that it is often difficult to locate the appendix during a second attack, and then the history of the first attack is the main guide to a correct diagnosis.

In the operative treatment of appendicitis a number of different incisions have been devised, but it must be admitted that often it is immaterial which incision is made. At times, however, according to the location of the appendix, one incision will give a better exposure than another. A correct diagnosis of the position of the appendix is therefore of aid in selecting the most suitable incision, while it also enables us to know where to look for the appendix during operation, thus preventing an unnecessary disturbance of the intestine.

TREATMENT OF FRACTURE OF THE NECK OF THE FEMUR.

THE general pessimistic belief that a definite attempt to secure restoration of form and function in cases of fracture of the neck of the femur is of little avail is easily explained when we read the unfavorable results generally reported. Thus Scudder writes that in only two out of sixteen cases of fracture of the neck treated by extension and immobilization was the leg functionally useful two and a half years after the accident. In the January number of the *Annals of Surgery* John B. Walker reports the results in 112 cases treated at Bellevue Hospital since January, 1906. Of these eighteen patients died; thirty-two had not been heard from; thirty were unable to work because of persistent impairment of function, through pain, restriction of movement at the hip on account of shortening and adduction, or the necessity of dependence upon crutches. Twelve had abandoned their crutches and were walking comfortably with a cane, but at times with stiffness and pain. They were beginning to do some work. Ten had recovered almost completely; they were free from pain and stiffness and were able to do their normal work. Ten were still in the hospital.

Of these 112 all but fifteen were treated by the long side splint and Buck's extension. Appreciating the impossibility of obtaining success with this old-time method, Walker used the method advocated by Whitman in fifteen cases. Under an anesthetic, which permits complete relaxation, the leg on the fractured side is gradually abducted to the normal limit of about forty-five degrees, the hip joint being held and supported. At the same time traction is made to overcome the shortening as much as possible. The pelvis is prevented from tilting upward by simultaneously abducting the sound leg to forty-five degrees. Outward rotation is corrected by lift-

ing up and supporting the upper end of the femur and rotating the leg inward. A plaster spica is then applied to include the pelvis, crossing below the edge of the ribs and including the foot to prevent any outward rotation. Walker lays great stress on the importance of making abduction complete, as it exercises direct traction upon the capsule, rendering it tense in front and below. As the capsule supports the sides of the fragments it tends to force them into alignment. He treats impacted fractures like unimpacted ones, *i.e.* he replaces the fragments in their normal anatomical position by carefully unlocking and separating them. Of the fifteen patients treated by this method, Walker reports four as cured at the end of from six to twelve months. They had no deformity, pain, or discomfort, had freedom of motion, and were able to resume their regular work. Five other patients who had been under treatment for less than four months were up and walking on crutches. Six patients had been under treatment less than two months. In no case was any harm done by the bandage. The patients could move about without pain and could help themselves in many ways, while patients with side splints and Buck's extension usually complain of pain whenever any movement is made.

The fact that thirty per cent. of the 112 patients treated at Bellevue were transferred from other hospitals, where they had been for less than a week, and that fifty-four of the 112 were discharged from the hospital within fifteen days after admission, betrays a degree of indifference to patients of this class. This indifference might be justified by the fact that the results of such carelessness are usually no worse than those obtained by long-continued treatment with a long side splint and Buck's extension. With the adoption of Whitman's method, to which Walker's good results are undoubtedly due, it is to be hoped that greater interest will be shown in these patients, especially as, from the hospital standpoint, this method of treatment is less exacting, in that the patients, being more comfortable, do not require so much time and attention.

PROPHYLAXIS OF HYDROPHOBIA.

That there should have been thirty-two deaths of human beings from hydrophobia in the Greater City of New York during the past ten months is something more than an unfortunate circumstance—it is not too much to say that such a record is a disgrace. This number, incredible as it may seem, is unofficially set down as a fact by one who speaks with authority and who knows whereof he speaks; therefore it can be taken as positive. Many complaints have been made from time to time, in letters to the press and in other ways, of the wholly superfluous horde of irresponsible cats and dogs that invade our streets, but few have realized that these animals are not only figuratively but literally pestiferous. As an actual menace to the public health it requires no great amount of research to prove that they are responsible for more deaths than smallpox, and this because they multiply so rapidly, are so widespread in their distribution, and are not properly under control. Clippings made from one newspaper in this city showed that during the thirty-one days of December, 1907, two adults and four children in the boroughs of Brooklyn and Manhattan were sacrificed by this entirely preventable disease, and it is probable that there were a few more cases at least which were reported in other papers or were not reported in any paper.

Still the war between the philozoics and the philosophers goes on, and the new-born puppy has as good or a better chance than most babies of the human variety in the struggle for existence. With the limited amount of funds in hand the Society for the Prevention of Cruelty to Animals has done reasonably good service for the community in this respect. During the past fiscal year it succeeded in disposing of 40,000 dogs and 70,000 cats, but these figures, startling as they are, do not convey any idea of the enormous number of animals still at large in the five boroughs. In 1903 an ordinance was passed making it a misdemeanor for an owner to allow his dog in the streets unless muzzled or led by a four-foot leash. This provision was seldom or never enforced, and was repealed in 1906. Consequently the city has no authority over dogs at this time save in the matter of requiring a license, which is nearly the worst measure that could well be contrived in so far as the prevention of hydrophobia is concerned, for after the owner has paid his license fee and provided his pet with a brass collar he feels that his responsibility has ceased, and the dog, being of an indiscriminating turn of mind in this regard, does not hesitate to contract rabies and confer hydrophobia upon his nearest human neighbor.

We learn that a committee of three has recently been appointed by the Washington Heights Medical Society to look into the matter of hydrophobia in Greater New York, and that as soon as the proper data can be obtained an attempt will be made to introduce a bill at Albany which shall provide for the proper muzzling of all owned dogs and for the destruction of all tramp dogs and cats. It is doubtful just how much can be accomplished in this way, but surely every medical man and every enlightened layman should heartily support any effort toward the complete stamping out of that absolutely preventable and one of the most horrible of diseases, human hydrophobia.

The Transplantation of Tissues.

The transfer of portions of the body of one animal to that of another is a problem that has long occupied experimenters. It is recorded that as long ago as 1793 Aldovandi succeeded in causing the spur of a rooster to grow on the head of the same animal, while in 1863 Bert was able to unite pairs of white rats by bridges of skin several centimeters in length. Eiselberg in 1889 found that it was possible to cause the skin of one rabbit to cover over denuded areas on the body of another but that the experiment always failed when animals of different kinds were used. The most recent work in this direction is that of Carrell who has removed both kidneys with their ureters and vascular attachments from cats and replaced them with corresponding organs from other felines, the transplanted urinary apparatus appearing to answer all the demands put upon it in its new host. Sauerbruch and Heyde (*Münchener medizinische Wochenschrift,* January 28, 1908) have gone to work in a somewhat different way and have

effected the union of pairs of rabbits whose abdominal walls were denuded and sutured together in various ways. In some of the experiments only the muscles were brought in contact, in others the abdominal cavities were opened and juxtaposed so that free communication existed from the one to the other, while in still others a lateral anastomosis was also done between two loops of large intestine. It was found that the experiment could not be made to succeed unless the animals were young, were of the same sex, and of the same litter. That the vascular union between the two individuals was complete was shown by the fact that on injecting such substances as potassium iodide or sodium salicylate into one animal it could be detected in the urine of both, while anthrax bacilli thrown into the circulation of one caused the death of both and could be recovered from the heart blood of both. In one instance one kidney was removed from one animal without apparent ill effects, but the removal of the second organ was followed by the prompt death of both rabbits, so that apparently the organs of the two were not able to functionate vicariously for each other. The considerations involved in a parabiosis of this sort are many and various and it is not unlikely that something of practical as well as theoretical value will result from their extension. The problems of immunity and serology especially would seem to be susceptible of investigation in this way.

The Treatment of Dysmenorrhea.

Of the minor gynecological maladies dysmenorrhea is one of the most prevalent and also most intractable. The list of remedies and plans of treatment advocated for its relief is a long one, but as is usually the case when many cures are recommended, none is altogether satisfactory. No doubt the fact that painful menstruation is merely a symptom that may depend on underlying conditions of widely different nature, is responsible for the difficulty that is often experienced in affording relief of the harassing and frequently incapacitating ailment. At least four different forms of dysmenorrhea may be distinguished, those depending on mechanical obstruction, those due to inflammatory conditions of the endometrium, those of reflex nature and emanating from the ovary or from extragenital organs such as the turbinated bodies or the eyes, and finally a group that for lack of more exact means of classification is regarded as a manifestation of a general nervous-hysterical tendency. A suggestion made by Polano in the *Münchener medizinische Wochenschrift*, August 27, 1907, might perhaps be expected to prove of service in the latter two types of the affection, and as it would seem to be entirely harmless, is worthy of trial in cases that have been found refractory to ordinary measures. It consists in endeavoring to influence the ovarian function by exciting the *quasi* antagonism existing between the mammary gland and the ovary. This is effected by the application to the breasts of the glass suction apparatus used in the treatment of mastitis by Bier's method. The suction is kept up for from fifteen minutes to half an hour daily, beginning some days before the expected onset of menstruation, and continuing it through the period. The relief to the pain has been very marked in the author's experience, and the duration of the flow is also reduced in many cases. The method has also been applied with advantage in cases of insufficient functional capacity during lactation, a few treatments sometimes sufficing to reestablish a lacteal flow that seemed on the point of ceasing absolutely.

Conjugal Diabetes.

Among the students of this mysterious disease there have not been lacking those who have regarded it as a transmissible affection and have cited as evidence in favor of this view cases in which man and wife have both suffered, or servants, laundresses, and others, shortly after coming into habitual contact with diabetics, have developed glycosuria. Senator in discussing this question (*Berliner klinische Wochenschrift*, January 27, 1908) says that the average of a very large number of cases of diabetes from the statistics of a dozen or more writers shows that the proportion of married couples is not more that about 1 per cent. Such a method of calculation is illogical, however, since in order to investigate the question of conjugal diabetes all unmarried patients should be excluded from the count and the length of time the two persons have lived together after the one member had manifested the first symptoms of the disease should also be regarded. Taking five hundred and sixteen married couples from his own private practice in which husband or wife was diabetic, under the most favorable method of estimation the other member was also diabetic in 4.3 per cent. Even this proportion, which is surely too high, as well as most of the isolated cases of apparent infection that have been reported, can be explained in other ways, while it must be borne in mind that animal experiments in this direction have been negative. Senator's conclusion is that there is little or no evidence in favor of a belief in the infectiousness of diabetes, though if only occasional cases are considered an offhand denial of this possibility does not seem justified. Since the affection generally known as diabetes mellitus is now believed by most pathologists to include an indefinite number of more or less different conditions it is perfectly conceivable that one or more types may occur whose etiology is such that transmission from one individual to another, that is to say, contagion, is possible.

Teleradiography of the Heart.

Promptly after clinical radiography had reached the practical stage attempts were made to apply the method to the determination of the exact size and contour of the heart. As the result of the recognition of the fact that, owing to the divergence of the rays, direct radiographs were open to criticism on the score of accuracy in regard to dimensions if not of form, various methods of causing the rays to travel in parallel lines were devised, culminating in the orthodiagraph of Moritz. This method, however, requires a rather complicated technique and is not free from subjective errors, disadvantages which Köhler (*Deutsche medizinische Wochenschrift*, January 30, 1908) has found so marked as to cause him to seek a substitute in what he terms teleröntgenography. This consists in making the exposure with the tube from one and a half to two meters from the body, a distance which is sufficient to obviate errors from parallax without being beyond the capacity, he says, of even a medium sized coil. Good negatives may be produced with exposures of thirty to forty seconds while with suitable apparatus this time may be greatly reduced. The depictions of the cardiac shadow obtained in this way are alleged to be trustworthy representations of the size and outline of the organ, while their production is much simpler than that of the orthodiagraphs.

News of the Week.

Presidency of the State Medical Society.—Owing to the fact that ill health makes it impossible for Dr. Edward L. Trudeau of Saranac Lake to act as president of the Medical Society of the State of New York, under Section 2 of Chapter VI of the by-laws, the first vice-president in numerical order, Dr. Arthur G. Root of Albany, becomes the president for the year 1908.

Medical Society of the County of Kings.—At the annual meeting of the society held January 21, 1908, the following officers were elected: *President,* Dr. Onslow Allen Gordon; *Vice-President,* Dr. Joshua M. Van Cott; *Secretary,* Dr. Henry G. Webster; *Associate Secretary,* Dr. William A. Jewett; *Treasurer,* Dr. John R. Stivers; *Associate Treasurer,* Dr. Henry M. Mills; *Directing Librarian,* Dr. James P. Warbasse.

Harvey Society Lecture.—The seventh lecture in the Harvey Society course will be delivered by Professor Otto Folin of the Harvard Medical School at the New York Academy of Medicine on Saturday evening, February 22, at 8:30 P.M. The subject will be: "Problems of Chemistry in Hospital Practice."

Hodgkins Prize of the Smithsonian Institution.—The Hodgkins Fund Prize is to be awarded next year for a paper on "The Relation of Atmospheric Air to Tuberculosis." In October, 1891, Thomas George Hodgkins, Esquire, of Setauket, New York, made a donation to the Smithsonian Institution, the income from a part of which was to be devoted to "the increase and diffusion of more exact knowledge in regard to the nature and properties of atmospheric air in connection with the welfare of man." In the furtherance of the donor's wishes the Smithsonian Institution has from time to time offered prizes, awarded medals, made grants for investigations, and issued publications. In connection with the approaching International Congress on Tuberculosis, which will be held in Washington, September 21 to October 12, 1908, a prize of $1,500 is offered for the best treatise that may be submitted to that congress on the above subject. The treatise may be written in English, French, German, Spanish, or Italian. The essays will be examined and the prize awarded by a committee appointed by the secretary of the Smithsonian Institution in conjunction with the officers of the International Congress on Tuberculosis. The Smithsonian Institution reserves the right to publish the treatise to which the prize is awarded. Further information will be furnished to intending competitors on application by Mr. Charles D. Walcott, secretary, Smithsonian Institution, Washington, D. C.

George Blumenthal, Jr., Fellowship in Pathology at Mount Sinai Hospital.—This fellowship has been established with a stipend of $500 per annum. All graduates in medicine are eligible. The term is one year. The fellowship cannot be held more than twice by the same person. The object of the fellowship is to further the scientific work of Mount Sinai Hospital and to aid those anxious to obtain a laboratory training. The work done under the fellowship is to be carried on in Mount Sinai Hospital or elsewhere under the direction of the pathologist. Applications may be sent to Dr. F. S. Mandlebaum, the pathologist of the hospital, before March 15, 1908. Committee: A. Jacobi, A. G. Gerster, F. S. Mandlebaum, E. Libman.

Tuberculosis Appropriation.—In his annual report, sent to the Legislature a few days ago, Dr. E. H. Porter, State Commissioner of Health, asks for an additional appropriation of $75,000 to be used in combating tuberculosis, and for $30,000 for the inspection of water supplies supposed to be sources of typhoid fever. The Commissioner estimates that there are annually in the State 50,000 cases of tuberculosis and 15,000 deaths, representing an economic loss of $70,000,000.

The Antituberculosis Movement.—At a meeting of colored people held in Chicago, February 9, 1908, an antituberculosis association was organized with a view to checking the spread of tuberculosis. The following officers were elected: *President,* Dr. A. W. Springs; *Vice-President,* Dr. A. W. Mercer; *Secretary,* Dr. A. W. Williams; *Treasurer,* Dr. George C. Hall.

Finances of the Chicago Health Bureau.—The Chicago Health Department suffered recently very materially at the hands of the City Council's Finance Committee in that the emergency fund of $50,000 asked for by Commissioner William A. Evans was disallowed, the argument being that in the event of emergencies in the protection of the community's health the Council could make a special appropriation. The appropriation of $50,000 for the abatement of nuisances by the Health Department was reduced to $5,000. Then, to round out its work, the Finance Committee took $50,000 out of the appropriation for the general running expenses of the department. This means that Dr. Evans must retrench in every way possible. Health measures he had intended to introduce will have to be abandoned and a number of employees will probably be dismissed.

A Mass Meeting of Antivivisectionists.—The quality of the arguments advanced at the meeting of antivivisectionists held in the Carnegie Lyceum a week ago may be gathered from the following extract from the address of one of the orators, who is reported as calling those who use animals in the course of scientific research "virtuosos of agony, in whom curiosity, vanity, or scientific zeal has supplanted humanity, and to whom harmonies or discords of agony or long-drawn cadences of torture struck from quivering nerves are music." The following curious preamble and resolution was adopted by acclamation: *Whereas,* It is the current belief, borne out by the statements published in the medical press, that the principal theater of vivisection operations in this part of the world to-day is the Rockefeller Institute for Medical Research in New York City, and its adjunct, the Rockefeller Farm, in Somerset County, N. J.; and *Whereas,* It is concurrently reported that the experiments on living animals conducted at these institutions are of a cruel and brutal nature: *Resolved,* That this mass-meeting, echoing a strong humane sentiment in the community, do respectfully petition Mr. John D. Rockefeller to reconsider his program and restrict vivisection in the institute bearing his name as being contrary to the humane sentiment of advancing ethical progress."

Not Christian Science.—Mr. J. V. Dittemorr of the Christian Science Committee on Publication writes that he has positive information that the child whose death under Christian Science treatment in Danville, Ill., was reported in these columns last week was never treated by Christian Science methods, "nor did any member of the family have even the slightest knowledge of the subject of Christian Science. This family seem to have been adherents of some sect which

did not believe in giving medicine, but Christian Science was in no way connected with the case."

Smallpox in Newburg, N. Y.—A number of cases of smallpox have been reported during the past week in Newburg, N. Y., one of the patients being the principal of a public school having eight hundred pupils. The Board of Health has closed this school and is transforming a large house on the outskirts of the city into an isolation hospital. The disease is of a mild type and is supposed to have been imported from Kingston, where there have been a number of cases lately.

Plague in Ecuador.—The State Department has received a dispatch from the American Minister at Quito to the effect that plague is prevalent in Guyaquil.

Influenza in London.—London is now the seat of an unusually severe epidemic of influenza, which many physicians say is the most serious the city has ever experienced.

Hospital Benefits.—At a special performance of "Aida" given last week at the Metropolitan Opera House for the French Hospital the sum of $12,000 was realized, a large part of which will be available for the needs of the hospital. The sum of $5,000 was raised for the Nassau, L. I., Hospital at a hospital matinee and tea arranged last week by Mrs. William K. Vanderbilt, Jr.

City Hospital, New York.—An examination of candidates for interne positions on the house staff of this hospital will be held on March 27 and 28. All applications should be addressed to the chairman of the examination committee, Dr. Smith Ely Jelliffe, 64 West Fifty-sixth street, New York City.

Robbery in a Hospital.—Two microscopes with their lenses were stolen from the laboratory of the Lincoln Hospital, in the Bronx, by a thief who broke into the building last week. He was later captured by the police and identified as a former employee of the hospital who had worked in the laboratory.

Against Quackery in Germany.—Active measures to suppress quackery are being contemplated in Germany. A bill has been drawn and has received the assent of the Council providing fines and imprisonment for irregular practitioners of all sorts and authorizing the prohibition of the sale of patent medicines whose ingredients are kept secret or concerning which fraudulent claims are made.

Physician Speaks From Pulpit.—At the regular morning service in the Third Presbyterian Church of Rochester, N. Y., Sunday before last, the Rev. Paul M. Strayer took as his theme "The Treatment of Moral Consumption," and was followed by Dr. William S. Ely, who delivered an address on the practical problems of the tuberculosis question. In the church calendars distributed at the service was incorporated a circular on tuberculosis issued by the Charity Organization Society.

State Charities Board.—Dr. Enoch V. Stoddard of Rochester, N. Y., has been obliged to resign from the State Board of Charities on account of ill health.

A New Journal.—With the title *The Archives of Diagnosis* an attractive-looking new quarterly appears under the editorship of Dr. Heinrich Stern of this city. It is devoted entirely to the subject of diagnosis, but everything relating to this branch of medicine will receive full treatment in its pages.

A New International Journal of Epilepsy.—Announcement is made of a new journal to be called *Epilepsia*, which is to be an international quarterly, devoted to the study and treatment of this disease from the therapeutic, social, aand judicial points of view. The editorial staff includes the names of H. Claude of Paris, Turner of London, L. Bruns of Hanover, W. P. Spratling of Sonyea, J. Donath of Budapest, who is the active editor for the first year, and L. J. J. Muskens of Amsterdam, secretary.

The "Relief" in Commission.—The hospital ship *Relief* has been placed in commission at the Mare Island Navy Yard, San Francisco, with Surgeon Charles F. Stokes in command. It is intended to have the vessel make a short practice cruise and then meet the fleet on its arrival at Magdalena Bay.

Tuberculosis Campaign.—The Russell Sage foundation has given $10,000 to the State Charities Aid Association for use in organizing methods for the prevention of tuberculosis in this State.

Bequest to Philadelphia Hospital.—By the will of the late Wm. H. Burns of Philadelphia the sum of $25,000 is bequeathed to the Frankford Hospital for permanent improvements.

In Honor of Pirogoff.—In order to commemorate the twenty-fifth anniversary of the death of Pirogoff the cities of Moscow and St. Petersburg have each named a street and a hospital in his honor and have founded annual Pirogoff prizes for research in surgery.

Death of a Centenarian.—The death is recorded in Philadelphia of a man at the advanced age of 108 years. He was a native of Hungary and had been in full possession of his faculties until within two weeks. He was a follower of Kossuth in the Hungarian rebellion of 1848 and he had been in this country for thirty-five years.

Des Moines Physicians' Club.—The following officers for the ensuing year have been elected by this society: *President*, Dr. W. W. Houser; *Vice-President*, Dr. W. W. Coleman; *Secretary*, Dr. H. S. Oyler.

Clay-Becker County (N. D.) Medical Society.—At the meeting of this society, held in Moorhead, the following officers were elected: *President*, Dr. E. W. Frazier of Detroit; *Vice-President*, Dr. A. H. Aborn of Hawley; *Secretary and Treasurer*, Dr. Barton of Frazier.

Muscatine County (Iowa) Medical Society.—The following were elected as officers for this society at the meting held in Muscatine on January 31: *President*, Dr. A. J. Oliver; *Vice-President*, Dr. E. A. Ady; *Secretary and Treasurer*, Dr. Fred L. Appel.

Johnson County (Neb.) Medical Society.—The annual meeting of this society was held in Tecumseh on January 25 and officers were elected as follows: *President*, Dr. C. H. Ziegler of Vesta; *Vice-President*, Dr. G. J. Rubelman of Tecumseh; *Secretary and Treasurer*, Dr. C. R. Snell of Tecumseh.

Italian Society for the Study of Tropical Diseases.—A society for the study of tropical diseases has been founded in Rome through the efforts of Professor Angelo Celli, director of the Institute of Hygiene of Rome, Surgeon-Lieutenant-Colonel L. T. Cipollone of the Italian Navy, and Surgeon-Captain G. Memmo of the Italian Army.

Somerville (Mass.) Medical Society.—The following were elected as officers at the meeting of this society held on February 6: *President*, Dr. C. L. Maguire; *Vice-President*, Dr. W. L. Bond; *Secretary and Treasurer*, Dr. I. E. Stowe.

Obituary Notes.—Dr. Eben N. Hutchinson of Charlotte, N. C., died on January 30, at the age of eighty-one years. He was born near Augusta, Ga., and was graduated from Davidson College in 1845. He was graduated from the medical department of the University of Pennsylvania with the class of 1848 and immediately began practice in Charlotte. For many years he had given up practice and had engaged in various mercantile pursuits.

Dr. B. S. Nichols of Pomona, Cal., died on January 27 at the age of eighty-four years. He was born at Enosburg, Vt., and was graduated from Vermont Medical College at Woodstock. Until 1850 he practised in Vermont and then removed to Whitehall, N. Y., where he remained until 1885. In that year failing health compelled his removal to California, where he had resided since that time.

Dr. Martin J. Dalton of Melrose, Mass., died on February 4 at Tryon, N. C., where he went some weeks ago on account of poor health. He was born in Marlboro forty-eight years ago and was a graduate of the medical school of the University of Vermont. About ten years ago he came to Melrose from Marlboro.

Dr. Hiram G. Wyckoff of Palo Alto died on January 28 at the age of sixty-eight years. He was a native of Illinois and served through the Civil War in the 124th Illinois Regiment. He was a graduate of the Rush Medical College.

Dr. S. E. O'Neill of Ottumwa, Ia., died suddenly on January 31 at the age of seventy-two years. He was coroner of Wapello County and died while preparing to hold an inquest on the death of a man killed in a mine accident. He had been a resident of Ottumwa for almost thirty years.

Dr. David L. Cedarholm of Brooklyn died suddenly on February 7 at the age of forty-five years. He was born in Stockholm, Sweden, and about fifteen years ago came to this country. He was graduated from the Long Island College Hospital in 1896.

Dr. John C. Barron of this city died of typhoid fever on February 6 at the age of seventy-one years. He was graduated from Burlington College and also from Yale, rowing on the first crew organized in 1858. He was graduated from the College of Physicians and Surgeons of this city in 1861, served during the Civil War as surgeon in the 69th regiment, and was surgeon of the 7th regiment until 1871. He retired from active practice many years ago and was a member of the New York Yacht, the Corinthian Yacht, the Shelter Island Yacht, Union League, and numerous other clubs.

Dr. Frank Hazzard Dye died at Philadelphia on February 3 at the age of thirty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1899. He was assistant surgeon to the German Hospital and to the Stetson Hospital.

Dr. Aaron K. Baldwin of Newark, N. J., died on February 9 after a long illness from cirrhosis of the liver. He was born in Newark sixty years ago and was a graduate of the New York University Medical School. He had practised in Newark for thirty-five years and for many years was connected with the National Guard as surgeon.

Dr. Stacy D. Williamson of Malone, N. Y., died suddenly on February 5 at the age of thirty-two years. He was graduated from the Syracuse University Medical School in the class of 1901.

Correspondence.

AN APPEAL TO THE MEDICAL PROFESSION OF NEW YORK STATE.

There are now in the Legislature not less than three bills relating to vivisection. There is one relating to optometry. Will you not write at once to your representatives in the Legislature, both Senator and Assemblyman, urging opposition to these measures?

The antivivisection bills, as they are called, are the work of the Antivivisection Society, and the desire is to prohibit animal experimentation. The claim is made that all animal experimentation is unnecessary and that the various discoveries of science made possible by this method of investigation have not been productive of good to humanity. This claim is proven incorrect by a plain statement of the facts from gentlemen of education, intelligence, and scientific attainment, professors in our various colleges, and scientists generally whose very names are synonymous with honor and integrity. They clearly show to any unprejudiced mind the inestimable value to humanity of the work which has been done, and is being done, along this line. The statement has been made that at present there is no restriction whatever placed by law on animal experimentation, whereas the fact is that there is now a law on the statute books which restricts the work to properly equipped institutions. If there have been isolated cases of violation of this law which have gone unpunished, the blame should be placed on those authorized to secure the law's enforcement.

The claim that great cruelty is inflicted on animals in these scientific experiments is denied absolutely and entirely by those in charge of experimental work in this State. There is really no reason for any enactment of a new law on this subject and this should be made very clear to the members of the Legislature.

The optometry bill is the old measure, and should be defeated. This bill defines the practice of optometry as the measurement of the powers of vision and the adaptation of lenses for the aid thereof, all without the use of drugs. This bill gives authority to opticians to do a work and at the same time prohibits the employment of the means necessary to do it. The bill authorizes opticians to adapt lenses to eyes for defects of vision which may be due to diseases in other parts of the body, or to diseases which may be situated in the eyes themselves. The adaptation of lenses to eyes under such circumstances, while improving vision for the time, may be the cause of deferring proper treatment until blindness or even death may be the result. To determine when defects of vision are due to defects in the eyes or to disease requires the ability to make a differential diagnosis, and this knowledge can only be acquired, according to the laws of the State of New York, by four years' study in a medical college. Possibly some restrictions ought to be placed on the work opticians should do, but to give them the power this bill would confer would be to expose the people of this State to perils the members of the Legislature cannot have knowledge of unless we inform them.

The members of the Legislature are honest, sincere men, and their desire is to do what will be in the interest of the State. They listen with great courtesy to the expressed opinions of the medical profession, and it will require conclusive evidence on the part of opticians and others to convince the Legislature that any of these bills are necessary, or even safe, if we in good faith urge disapproval of them.

Will you not therefore at once do what you can in aiding us in defeating these measures by writing the members of the Legislature, that they may be able to act intelligently. (Signed) Frank Van Fleet,

Chairman Committee on Legislation, Medical Society of the State of New York.

THE TREATMENT OF NERVOUS INVALIDS.

To the Editor of the Medical Record:

Sir:—Dr. Frank P. Norbury quotes from my letter on Fletcherism the question if there are many sanatoriums in which the physicians make more than a shallow pretence at finding the real cause for a neurasthenia, and he asks in reply if there are many surgeons who make more than a shallow pretence at finding out the real cause in similar cases. His point is well made. Some time ago a physician in a small town was expatiating upon the general superiority of physicians in such towns, and I asked him if the remarks applied to himself, or to the three other doctors in the same town. The matter gets

down to the *argumentum ad hominem* after all. I know of sanatoriums where a comprehensive study of the patient is really made. Does Dr. Norbury know of any of the other sort? I know surgeons who do not operate upon much more than half of the number of patients who are sent to them for operation, even though the fee is ready, and considerable diplomacy is required to avoid offending the doctors who have sent the patients for operation.

Any surgeon who is right minded and properly equipped is keenly alive to the presence of a psychoneurotic patient in his office, and mighty few such patients get operated upon unless there is strong presumptive evidence that some surgical feature may be a precipitating factor in the case. A pretty good rule is to operate only for such conditions as would call for operation anyway, for anybody. Take hernia or well selected cases of loose kidney for instance. These are cases in which the surgeon can lighten the work of the internist, even though he does not cure the grandmother who transmitted psychoneurotic tendencies to the patient. Knowledge is a handy thing to have in the house. The sum total of knowledge since the days of Alexander von Humboldt has become so unwieldy that we doctors must now follow the example of the lawyers in contenting ourselves with knowing who knows. At the meeting of the Medical Society of the State of New York, on January 29, while the discussion of gastric neurosis was under way, I was strongly attacked for saying that we must regularly eliminate the possible factors of eyestrain, involuting appendices, and bile-tract adhesions, before proceeding to treatment in these cases. Speakers denied that we should even try to get negative testimony upon these points. The difference between firmness and obstinacy has been defined. Firmness is will power, and obstinacy is won't power. God help the dyspeptic patients of the doctor who carries his problems to the *x* power of won't.

A loophole through which diagnoses slip out, occurs in the offices of men whose diagnostic acumen is such that they are overcrowded with work. I have seen in one year four cases of cancer of the rectum that had come from the office of a famous consultant, undiagnosticated. If anything so tangible as cancer of the rectum gets away, how many nervous invalids will have eyestrain hit with the diagnostic arrows? I decline to be classed as a hobbyist because it has seemed to me to be best to send patients to various experts, before proceeding to operation, in many cases.

Internists and surgeons should not indulge in mutual recriminations, because we each see so many cases in which the other side was unobservant. Recriminations belong to the negative, and are consequently destructive. Positive and constructive appreciation of the fine work done in both fields is required if we are to believe that the ideals of our profession are ideals of intellect and of character. We shall always have a herd of people following the psychoneurotic leader of the day, and in two notable cases the leader has been a bellwether—Joan of Arc and Mrs. Mary Baker G. Eddy. The one was victorious in the martial arena, and the other has been victorious in bringing happiness to hundreds who were afflicted with the contagious disease known as nervous prostration. Instead of giving nervous prostration to every one with whom they come in contact, these patients who follow the leader now morbidly carry the suggestion of hope.

We shall be sorry when Mrs. Eddy dies, for the Christian Scientists, like the followers in other similar movements, will rapidly disband, and will go to smash over questions of leadership and of disposal of funds. Fletcherism stands ready to call together some of the scattered herd, and it may be expected to stand at least as an overchewer to some other play. We already have the nomenclature of "divine mastication." I have patients who would call a daily movement of the bowels divine if they could get it. Anything that can catch and hold the appellation of "divine" will march off with the nervous invalids whose precipitating causes for psychoneuroses are overlooked by sanatorium physicians—and by surgeons.

I once heard a surgeon say to a neurologist that he could clean out his office in thirty days—to which the neurologist replied that he had no doubt of it. We ought to clean up each other's offices, at least, and it is our own fault and no one's else right now if undiagnosticated cases of nervous invalidism are allowed to flock to flags of faddists. The requisite amount of knowledge is extant, but the diffusion current of controversy and the short circuit specialists take the main current off the wire.

Robert T. Morris, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent

HARD LABOR FOR CONSUMPTIVES—OPSONIC INDEX DURING EXERCISE AND WORK—SUBPHRENIC ABSCESS—LIVERPOOL TROPICAL SCHOOL—OBITUARY: PROFESSORS ANDERSON AND PETTIGREW.

London, January 31 [illegible]

The sanatoria have overturned a good many notions. It has long since been admitted that life in the open air, though a most important factor, was not the only cause of their success. Exercise soon claimed a share and graduated walking has been pushed in suitable cases to an unexpected extent—some patients benefiting by systematic climbing of hills. Still one would hardly expect an advanced patient could perform hard labor, however carefully graduated. This has now been done in a number of cases at the Frimley Sanatorium, established in connection with the Brompton Hospital some two and one-half years ago. Dr. Marcus Paterson was appointed to organize the new establishment, and has now reported to the Medical Society of London on the treatment by severe exercise which in suitable cases he has successfully carried out. He tells that he had noticed while resident in the Brompton Hospital that many patients continued up to their admission their usual occupations, and some of these were by no means light. One case he mentioned was that of a navvy who had a few days before admission worked for forty hours with scarcely any rest and did not seem any worse for it. Many general practitioners could testify to similar facts. Indeed, I think it is a common observation that consumptives constantly continue work long after they are advised not to do so.

Dr. Paterson concluded that if under adverse circumstances patients could thus act without injury they might, under ideal conditions, undertake useful work, graduated according to their physical state. He carried out the idea at Frimley, watching the effect of exercise on the patients, some of whom were at first averse to the treatment, as it was so contrary to their expectations. But their prejudices yielded to their experience, as they found they had only to take such exercise as was well within their powers—some, in fact, had to be restrained from doing more than was ordered. The system has been fully elaborated, and each patient on admission is told he will be treated by exercise and rest and that he must precisely obey the medical officer in both respects, as he cannot himself know what rest or what exercise is required in his particular case.

If a patient on arrival has a temperature of 99° he is put to bed and not allowed to get up until it has fallen below that point. So whenever in others the temperature rises to 99°, rest in bed is ordered. When exercise is begun it is watched carefully—walking up to one-half a mile a day may be tried for a week if no rise takes place. This may be gradually increased by one-half a mile at a time up to as much as ten miles. But at any stage of the gradation a rise in temperature is a call for rest until a fall.

The grades of work which have been elaborated at Frimley may be summarized thus: (1) Carrying baskets of mould or other material; (2) using a small shovel; (3) a large shovel; (4) using a pick-axe. In either of these grades the work is done for four hours a day. A fifth grade is using a pick-axe for six hours a day.

Dr. Paterson considers the basket work the most important of all, and it is a link between walking and labor. It is graduated into three sections by the load (12, 18 and 24 pounds), carried 50 yards up a gradient of 1 in 10.7, *i.e.* a rise of 14 feet in the distance.

The conclusions submitted are that: 1. Suitably selected patients can be gradually trained to do the hardest navvy work for six hours a day, the result being that their general condition is much improved, while some lose their sputum and their bacilli. 2. Certain patients who do not improve on light work show marked improvement on harder work. 3. Those who have slightly overexerted themselves and are kept at rest for the few following days are subsequently not only no worse, but may be in their own opinion better.

The clinical observations at Frimley have for the latter part of the time been checked by laboratory research. Dr. A. C. Inman, superintendent of the Brompton Hospital laboratory, undertook the determination of the opsonic indices of the patients, and he has detailed the results in a separate paper read at the same meeting. Every precaution seems to have been taken to secure reliable results. The personal equation was excluded, as Dr. Inman did not know on whose blood he was working, the specimens being dis-

tinguished by numbers only. Sir A. Wright's work on autoinoculations and immunization appeared to furnish an explanation of Dr. Paterson's success. The far-reaching importance of autoinoculation, spontaneous or artificially induced, might well explain the effects of the graduated labor as seen in the clinical records. Sir A. Wright lays down that autoinoculations follow all active or passive movements which affect a focus of infection and all vascular changes which activate the lymph stream in such a focus. The work done by a patient would, therefore, cause autoinoculation, and this was corroborated by the rise of the temperature and improvement of the patient thereupon. It was often found that patients who were not improving on one grade of work began to do so when a harder task was given. Of course in graduating the work it is possible that sometimes an excessive autoinoculation may be produced, but this will be transient and amenable to treatment by rest. To summarize the results we may say that the laboratory work has confirmed the clinical to a remarkable extent. The value of Dr. Paterson's graduated labor treatment has been submitted to a new scientific test. The opsonic index has shown that exercise can be graduated so as to give just the stimulus needed and can control it as to time and amount.

The discussion on these two papers—if so it may be called—amounted to very little. The President, indeed (Dr. J. K. Fowler), declared they worked an epoch in the treatment of phthisis and further they showed what he had constantly observed that consumptives did not recover under treatment by sports and games, for by them the amount of exercise was not controlled. It was now obvious why such patients got pleurisy from the undue fatigue.

Sir Almroth Wright thought tuberculin treatment was preferable, inasmuch as it could be commenced with minimum doses and increased as might be desirable.

Dr. Maguire observed that it must not be forgotten that the patients must be selected with the greatest care. Otherwise the treatment would fail.

Dr. Poynton said there was more in the sanatorium treatment with graduated exercises than in the autoinoculations induced.

Dr. Paterson, in reply, said tuberculin treatment did not so restore the patient as to fit him to resume his usual work, and Dr. Inman added that tuberculin injections could not equal sanatorium treatment with artificially induced inoculations by means of graduated exercises.

To the surgical section of the Royal Society of Medicine Mr. H. L. Barnard has contributed an instructive paper on subphrenic abscess founded on 76 cases treated at the London Hospital, 21 under his own care. To have clear ideas of the varieties he divided the subdiaphragmatic space into six areas, of which four are intraperitoneal. Gastric ulcer caused one-third of the cases, the appendix one-sixth, hepatic abscess one-sixth. Spontaneous rupture took place in 23 cases, 4 into a bronchus, 2 into the right pleura, 3 into the left, 1 into the peritoneal cavity. Of the 76 patients 36 or 47 per cent. died. Of 12 not operated on all died; eliminating these the figures work out at 37 per cent.

Mr. Barnard thought that all except 12 might have been saved in ideal circumstances, and so deduced an unavoidable mortality of 16 per cent. He thought it dangerous to operate in the diffuse stage and waited two or three days after diagnosis for the inferior pleural angle to become obliterated. The mortality of posterior operations was less than that of anterior. With pus in the right anterior intraperitoneal space, the liver was not pushed down so as to be recognized below the rib margin, but was held up by adhesions. In many cases the temperature was low, but it generally rose to 99° or 100° at intervals. Leucocytosis he found whenever it was looked for. The heart was pushed upwards, not laterally, as in pleurisy. In 56 of the cases empyema occurred. In one case he found x-rays helpful, but he regarded the history of the onset as the chief indication; at the onset there was an "acute abdomen complex." Pleural effusion in these cases he regarded as on a par with hydrarthrosis seen in an infective focus at the end of a long bone—a defensive bathing of tissues threatened with invasion by antibacterial serum.

Dr. De Haviland Hall referred to the importance of early diagnosis, as cases left alone always died.

Dr. Donald Hood regarded fulminating pleurisy as indicating trouble below the diaphragm, and said in eight cases no symptoms pointed to the stomach, although they were really due to gastric perforation.

At a meeting of Liverpool medical men on Saturday, Sir Alfred Jones was present and spoke of the work of the Liverpool School of Tropical Medicine which he thought set the world studying the subject. Liverpool had spent £80,000 on it, and a splendid investment it was, for it had saved thousands of human lives and brought down the African death rate from 30 to 2 per cent. It had enabled Europeans to live safely in Africa and had thereby caused that country to receive a better class of Europeans. The school was now investigating sleeping sickness, which, unless checked, threatened to depopulate the continent.

Sir T. McCall Anderson, Regius Professor of Medicine in the Glasgow University and physician to the King in Scotland, died on Saturday night. He was seized with heart failure at the conclusion of the Burns' anniversary dinner. He graduated at Glasgow with honors in 1858 and after further study on the continent commenced a career as physician in Glasgow which has all along been highly distinguished. He was physician to the Royal Infirmary and other institutions. From 1874 to 1900 he was professor of clinical medicine. In 1903 he represented the university in the general medical council. He was knighted in 1905. A practical physician and teacher of the first order, he was also a highly skilled dermatologist. He published a work on parasitic skin diseases which reached a second edition in 1868, an analysis of 11,000 cases in 1872, and other works in this department, a volume of lectures on clinical medicine in 1887, and contributions to this subject in 1898. Various articles from his pen on clinical subjects appeared in the medical journals throughout his career.

Yesterday Scotland lost another eminent professor of medicine by the death, after a long illness, of Jas. Bell Pettigrew, M.D., LL.D., F.R.S., Chandos Professor of Medicine and Anatomy in the University of St. Andrews. He was seventy-three years of age. In 1860 he was Croonian Lecturer to the Royal Society and President of the Royal Medical Society, Edinburgh. From 1862 to 1868 he was assistant curator of the Hunterian Museum at the Royal College of Surgeons of England, and in 1869 he took the curatorship of the Edinburgh College. In 1874 he was awarded the Godard prize of the French Academy of Sciences. From 1883 to 1887 he was examiner in anatomy at the University of Glasgow. The St. Andrews professorship he has held since 1875. He had served as dean of the faculty. He was a Laureate of the Institute of France and the recipient of many other honors. He was a prolific contributor to medical and scientific publications, the Philosophical Transactions of the Royal Society and the proceedings of various other societies, as well as the medical journals, being frequently enriched by his communications.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MEASLES AMONG THE NATIVES AND IN THE ARMY—CHOLERA—DIPHTHERIA—THE X-RAY IN LEPROSY—PERSONAL.

MANILA, P. I., December 28, 1907

SINCE the public school building which the American children attend has been closed, measles among this nationality has disappeared almost entirely. A more thorough inquiry among physicians that have practised in the Philippine Islands for more than twenty years reveals the fact that measles has been extremely common among the Filipinos, and that they have not been so immune as they were heretofore thought to have been. Measles among the Filipinos seems to be extremely benign, rarely ever resulting in death, and only in a few instances leaving bad sequelæ. In fact, the disease is so mild that it is an extremely rare thing for a child to be confined to bed or even to the house on this account. It is generally held, however, that if the American measles, which is unquestionably more severe in form, should infect the Filipino population, a much more serious epidemic might result. For that reason, it appears to have been a wise precaution to close the American school. Measles is continually introduced here by the troops, and it is perhaps worthy of note that not one organization that traveled as a regiment has arrived here during the past seven years from the United States without measles having made its appearance among them at some time during the trip.

Cholera still continues to occur in sporadic form in the provinces along the railroad which runs out of Manila, and averages about ten cases per day in as many different towns. For the week ending December 28, 1907, there were

five cases, and four deaths in Manila. Cholera has again been reported near the shores of Lake Lanao, Mindanao, and is said to be spreading toward Iligan and Malabang. The newspaper reports to the effect that Assistant Surgeon Greenleaf, who is on duty in that section, had been stricken with cholera, are erroneous.

The diphtheria situation has shown considerable signs of improvement. The cases that have occurred during the past month have been promptly isolated, the contacts injected with diphtheritic antitoxin, and thorough disinfection carried out in the premises in which they occurred, all of which seems to have a most important bearing in bringing this disease to a standstill.

After more than a year of painstaking effort, with the use of the *x*-ray regularly applied to some twenty odd lepers at the San Lazaro Hospital, there are again some satisfactory results to record. It is understood that these will be published shortly. It is now known that at least two cases are apparently cured and have been negative upon repeated microscopic examination, so that it has at least been demonstrated that even though the cure may not be permanent, yet satisfactory clinical results can be obtained with this form of treatment, and the unfortunate who contracts this disease is not entirely doomed and at least has the prospect of looking forward to something which will arrest its progress and result in the relief from the disfigurement, and produce a cosmetic effect which will assure him against being continually pointed out as a leper.

Captain and Assistant Surgeon Chas. R. Reynolds, U.S.A., who has been on duty during the past year at Fort McKinley as instructor and officer in charge of hospital corps companies, in which position he achieved considerable success, has completed his tour of duty in the Philippines and will return to the United States upon the transport which sails from here January 15, 1908.

The two officers, Captain and Assistant Surgeon Percy M. Ashburn and Lieutenant and Assistant Surgeon Chas. F. Craig, who have heretofore composed the Army Board for the Study of Tropical Diseases, have completed their tour of duty in the Philippines and returned to the United States. The new board will be composed of Captain and Assistant Surgeon James M. Phalen and Lieutenant and Assistant Surgeon Henry J. Nichols.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 6, 1908.

The Treatment of Leukemia with the Mixed Toxins of Coley.—Four cases are detailed by R. C. Larabee. One showed a degree of improvement amounting to symptomatic recovery which has lasted for over four months. Another has shown considerable temporary improvement. A third improved only in weight and general condition. A case of the acute lymphatic type was uninfluenced. Two are still under treatment but there does not seem to be much hope of permanent cure. The author declares that the results justify further employment. At the same time he warns the profession that this remedy in this disease is a very powerful agent. The dosage that one would use in sarcoma is not tolerated here. The initial dose should not exceed a tenth of a drop. It may be given daily at first, the dose being slowly increased. In the cases reported the interval was lengthened as soon as the reactions began to be severe, whether local or general. Severe chills sometimes occurred after a quarter of a drop, and in one case the reactions were so severe as to cause considerable alarm. Certainly, in the writer's cases, good results were obtained without such reactions, though it is possible that more lasting benefit might have been produced had the toxins been administered with greater boldness. If at any time in the course of treatment it becomes necessary to change the preparation or get a new supply, the dose of the new lot had better not exceed half that of the old, since different preparations differ greatly in the intensity of their effects. The effect of the injections on the anemia was marked, the latter being decidedly benefited. Apart from the definite reactions following overdoses, there was no fever. In fact, in one instance, the fever present as a feature of the case was markedly lessened by the injections.

General Paralysis As a Menace to Public Safety in Transportation.—Commenting on the loss of life and limb on American transportation systems, P. C. Knapp records the findings as to occupation in 50 cases in male adults who were in attendance at an out-patient department for various diseases. Five were in public transportation service, four in street traffic and one a boatswain in the merchant marine. Two were stationary engineers. The author points out the menace to the public welfare from having in such responsible places those who are suffering from early brain disease with more or less mental impairment. In such men there is a temporary failure of the brain to work with its normal accuracy. For some reason the man, although he knows the meaning of the signal, and has the visual power to see it and knows what he ought to do in response to that signal, fails to act. In some cases this failure is due to the fact that the man has been obliged to work an excessive number of hours on a stretch, as some of the quotations given above show. It is well known that indulgence in alcohol will cause such a failure, and therefore most railroads demand that their employees shall abstain totally while on duty if not altogether. We also know that, in the early stages of general paralysis and certain other chronic diseases of the brain, perception and memory are impaired, comprehension becomes more difficult, judgment is enfeebled, and action is less prompt. A railway employee with one of these diseases may therefore fail to understand his orders quickly and correctly and act intelligently according to his directions. In other words, as a consequence of his disease, he may be guilty of negligence which may lead to loss of life. The author says that there is little doubt that if men in responsible positions were examined by proper neurologists at regular intervals, many of these incipient cases of brain disease would be brought to light and the dangers attendant on them would be averted.

New York Medical Journal, February 8, 1908.

Indications for Water in Childhood.—M. Barbour gives a summary of the influence of water on the various bodily functions and makes a plea for its greater internal use in children. The healthy infant of several months should take a full glass in the course of the twenty-four hours, the amount being varied according to the weather. The amount should be increased in all conditions accompanied by elevations of temperature. It will restore the loss sustained through the fever, enhance the glandular activities, and by the dilution of the food will enable the gastroenteric tract to absorb more readily the nutriment and so will maintain vitality. Its use in local gastrointestinal maladies is too well known to call for more than mention. In bladder instability due to concentrated and acid urine water will prove of unquestionable benefit. In laryngitis and bronchitis, its ingestion will moisten the bronchial mucous membranes, liquify the viscid expectoration, and act as a mild expectorant. There are, however, certain conditions where the restricted use of water is clearly advisable. Such cases as edema or pleuritic effusion where the extravasation of fluid into the tissues is great, water is certainly contraindicated. In cases where there is a high arterial tension with congestion or inflammation in certain organs, such as the brain in meningitis, or the lungs in acute lobar pneumonia, an increased ingestion of water will aggravate the condition by additionally distending the blood-vessels, and the withdrawal of water is unquestionably the proper treatment. In fact, in any condition where there is congestion in important organs as a result of acute inflammatory processes, the use of large quantities of water is contrary to good judgment.

Therapeutic Use of Soured Milk.—H. Emerson says that the use of soured milk is based on three distinct properties: (1) The fact that pathogenic bacteria do not thrive in a medium that has a marked degree of lactic acid. (2) The process of carbohydrate and proteid disintegration occurring in the souring of milk makes a softer and more digestible and smaller casein curd, and a carbohydrate in a state of partial digestion. (3) Lactic acid activates peptic secretion and digestion. If we are to use soured milk, we must have: (1) Clean, whole milk. This is a necessary prerequisite if we wish to avoid the necessity of pasteurizing or sterilizing the milk before we start the process of souring. (2) The milk should be skimmed fresh, preferably by mechanical centrifugal separation immediately after chilling, subsequent to milking or during the process of chilling. (3) If the milk is not free from pathogenic or putrefactive bacteria it must then be sterilized, to put an end to the growth of pathogenic and putrefactive bacteria, and to enable us to control the results of our subsequent inoculation without the interference of undesirable organisms. (4) The milk should then be inoculated with an exact dose of biologically standardized bacteria. Probably the inoculation with bacteria should be accompanied by inoculation with known cultures of yeasts. The yeast is necessary: (1) To inhibit the overgrowth of pathogenic and putrefactive bacteria; (2) to add flavor which cannot be obtained without it, presumably by the production of aromatic substances such as esters; (3) to attack milk sugar after lactic acid has been formed in the milk, and produce alcohol and carbonic acid gas, which are valuable assistants in the digestion and ab-

sorption of milk and in making milk tolerated by irritable and congested mucous membranes.

Uric Acid: the Formation, Elimination, and Effect on the General System.—E. E. Smith reviews our knowledge on the subject of uric acid, dwelling particularly on its purin origin from the nucleic acid constituents of body cells. The quantity of the uric acid which appears in the urine is the resultant of the following operative factors: (1) The formation of uric acid (*a*) by endogenous purin metabolism; (*b*) by exogenous purin metabolism; (*c*) possibly in a slight measure by uric acid synthesis. (2) The destruction of uric acid by uricolytic ferments, particularly in muscle, kidney, and liver. (3) The retention of uric acid (*a*) by deposition in the tissues; (*b*) by limited excretory capacity. As to its effect, it is stated that it has but a slight degree of toxicity. Aside from the instances in which it is deposited in the tissues, as tophi, infarcts, or as embedded crystals, and produces mechanical injury, it is not known to cause any pathological condition. It is eliminated in increased amount in many pathological states, but this is the result of processes already discussed rather than evidence of its etiological relation to such disease conditions. But as an infarct or calculus or in the form of irritating crystals we cannot question its injurious action. As to the relation of uric acid deposits to the slight local necrosis which accompanies their deposition there is reason, though inconclusive, to attribute the necrosis to the action of the urates. The fact that joint cartilage has a special affinity for urates seems established, and it is reasonable to believe that the deposition results because of this affinity and because of the excess of uric acid in the blood. The cause of the excess may be increased formation, diminished destruction, and, probably most important, diminished elimination.

The Hand as a Therapeutic Agent.—An interesting paper is presented by J. M. Taylor in which attention is called to useful auxiliary measures which physicians may themselves employ with great advantage by adaptation of manual therapy, nerve pressure, massage, passive movements, chemotaxis, etc. The medical profession is as a rule very ignorant on the subject of manual treatment. Few physicians possess fair motor intelligence. Refinements in the education of touch, the perceptive hand will form an essential part of clinical diagnosis as well as of therapeutic teaching of the future. Any physician of moderate deftness can acquire enough skill to enhance greatly his own usefulness, but motor intelligence is not always on a par with intellectual gifts. In massage the following points must be borne in mind: (1) The rate of movements; of paramount importance are deliberation, nicety of rhythm, and confident gentleness; overrapidity is usually disturbing. (2) Depth and graduation of pressure; this should be nicely adjusted, and increased to the degree and amount required. (3) Quality of skin touch; whether dragging on the surface, pulling on superficial structures, hairs, etc., or (what is correct) firmly holding the surface tissues, seizing in turn layer after layer, with increasing grasp, while proceeding deeper, as the séance progresses, using the upper tissues to influence those underneath, till the lowermost are reached. (4) The length of time consumed. The customary full hour is often too much; an adept can do all that is needed in forty to fifty minutes, often less; more is fatiguing, often exhausting to frail persons. Subjects who "enjoy all they can get" are welcome to it; nevertheless, even then it may readily induce hurtful byeffects. (5) The kind and degree of exposure of the parts has much to do with the results. Each part should be covered immediately after treatment with a warm fabric, usually a blanket. Some persons suffer violent vasomotor reaction after massage, become chilled, or sweat profusely, or experience an extreme prostration. (6) General massage is exhausting to many invalids, especially to convalescents from infection, or to especially fragile persons, and in proportion as subjective overtension is maintained. It is an evidence of capacity in an operator, more often instinctive than acquired, to induce and maintain complete relaxation in the tissues of the subject. The foregoing are a few of the many interesting points brought out by the author.

Journal of the American Medical Association, February 8, 1908.

Gastric Ulcer.—W. F. Cheney holds that many cases of so-called chronic dyspepsia, characterized for weeks or months by flatulence, water-brash, burning and distress after food, where the epigastrium shows tenderness and the test-meal hyperacidity, are in reality gastric ulcer, even when the feces show no occult blood. If, in such cases, a month's ordinary treatment for the condition does not cause improvement, he has learned to insist on a rigid course directed to the cure of ulcer, even though no positive evidence of its presence has yet appeared. He reports several cases and gives his conclusions, not from these merely but from his experience with the groups they represent, substantially as follows: 1. There is an early stage of gastric ulcer, lasting for weeks or months, during which rigid medical treatment can effect a cure; but its clinical picture does not correspond to the classical one and the diagnosis at the time must be inferred rather than positively demonstrated. 2. In the later stage, commonly described as gastric ulcer, the symptoms are really due to complications rather than to the original disease; (*a*) to perigastric adhesions; (*b*) to pyloric stenosis; (*c*) to gastric dilatation and retention; (*d*) to localized peritonitis (*e*) to the opening of a large blood-vessel; (*f*) to perforation of the stomach wall—complications beyond medical treatment and falling into the surgeon's domain.

Ambulatory Treatment of Hip-Joint Disease.—E. G. Abbott and H. A. Pingree review the different methods of the mechanical treatment of hip-joint disease, and point out that no one method embodies all the essential principles. In order to secure the requisite fixation, traction and protection without too great expense, it will be necessary to combine the features of those in common use, and turning to those analyzed, he finds that the plaster-of-Paris spica bandage affords the best fixation, the adhesive plaster straps the best traction, and the iron brace which extends beyond the sole of the boot, together with the high shoe on the opposite foot, and crutches, the best protection. The cost of this combination amounts to about $5.75 for a child of average size. Details are given for the application of this combination and the objections to its use reviewed. The clinical results with this apparatus have been very satisfactory. About 200 patients have been under observation and their progress noted, and comparisons have been made with patients treated by the other methods. The authors' conclusions are summarized as follows: 1. The patient is under excellent control, as the apparatus cannot be removed and replaced by the patient or family at will. 2. The appliance can be produced at much less expense than any other that is efficient. 3. The duration of the treatment may be lessened, which is a factor to be thought of; there is less danger of abscess formation, and the preservation of the joint structure is more certain. 4. Finally, the position of the limb can be regulated to a nicety otherwise obtained only through the use of expensive apparatus accurately adjusted by skilled hands and kept constantly under the closest supervision.

Etiology of Epithelioma.—A. E. Hertzler proposes a chemical theory of the origin of epithelioma based on the hypothesis that "the epithelial cells are held in restraint by a chemical difference between them and the underlying connective tissue, probably the basement membrane or its equivalent, and that in malignancy there is a disagreement of the balance, usually by a lessening of the acidity of the connective tissue." He adduces a number of clinical facts in support of this hypothesis, all based on the assumed predominance of the alkalinity at the points where cancer occurs. His conclusions are summed up by him as follows: "1. Cancer occurs at that point where irritation and exposure to an alkaline secretion coexist. 2. When a chemical which has the power of combining with the acidophilic elements is injected into a tissue made up of epithelium and connective tissue the epithelium proliferates and invades the connective tissue, simulating the process in beginning epithelioma. 3. The same chemical process which prevents blood from coagulating limits the invasion of one tissue by another. Epithelium everywhere rests on a tissue similar to the membrane elastica of the blood-vessel. It is this layer that confines epithelium within the normal limit. 4. The aberrant growth of cells is but the expression of some disturbance in the chemical relationship of the different kinds of cells. The results of experiments, based on the knowledge of tinction chemistry, permits us to state in general terms the nature of such disturbance of chemical balance."

The X-Ray in Oral Surgery.—G. E. Pfahler describes a focusing device for the *x*-ray tube which, with slight modification, is applicable to any diaphragm, does not expose the operator to the ray, is convenient to operate, and renders results accurate. It consists of a piece of sheet iron or lead that will exactly cover the diaphragm opened. To the center of this is screwed a piece of brass tubing 8 in. long and ¼ in. bore, which is arranged to contain a second piece of tubing similar to a telescope. For use with the Roentgen table the sheet iron is made square, 13.7 c.m. (about 5½ inches), which exactly fits into the diaphragm clamp. To the center of this is attached the telescopic tube. This is then adjusted so that the rays pass through the tube on to a fluorescent screen lying underneath. The focus point will have to be exactly over the center of this tube or no rays will pass through. Having found the position of the Roentgen tube that will

exactly allow the rays to pass through the brass tube and cast a circle on the screen, the operator knows the focus point is exactly central. The Roentgen tube is then marked by a piece of adhesive plaster so that it can be replaced at any time in exactly the same position. This focus finder is then removed and the diaphragm replaced. The focus point will be exactly in the center of the diaphragm. He finds this device of great value, especially in oral surgery, where small, sharp fields are desirable. By careful technique he thinks every portion of either jaw can be clearly shown on the plate, and gives directions for photographing the different regions. Necrosis of the bone as well as malformations and malpositions of teeth can be clearly shown, and the exact lines of fractures determined. The condition of the antrum of Highmore can best be studied by this means, and it is a valuable aid in the diagnosis of malignant disease. Pfahler holds that every obscure condition should be tested by the *x*-ray, which should also be used to determine exactly the extent of disease, even when the general diagnosis is clear. By this, much embarrassment and suffering will be avoided.

Complications of Alcoholism.—L. D. Frescoln says that alcoholism of itself is a manageable affection from a medical point of view, and that it is in the accidental complications and sequelas that we find trouble. He enumerates about twenty disorders which he thinks can be properly considered such, as observed by him in 2,000 cases in the Philadelphia General Hospital. The chief of these, besides delirium tremens, are the different types of nephritis, pneumonia, pulmonary tuberculosis and myocarditis. Besides these there were observed a large number of morbid conditions recorded as complications, but which were merely associated or accidental troubles running hand in hand with the alcoholism, and perhaps antedating it, but not pathologically its consequence. There were also many probable defects in the records due to oversight, etc., and the figures are therefore somewhat deceiving. Only four cases of arteriosclerosis, for example, are recorded in the 2,000, while the condition, he thinks, must have existed in a very large percentage of the cases. The habits that go with alcoholism are important factors, and explain many of the complicating and incidental diseases; of course as a contributing factor to disease, there is the greatest difference between the use of alcohol and the condition called alcoholism.

The Lancet, February 1, 1908.

Open Safety-pin Removed from the Esophagus of a Child Aged Five Months.—D. B. Paterson considers that the use of probangs in such cases is an obsolete method and makes a plea for the modern direct method of esophagoscopy. In the present case, having ascertained the situation of the point of the pin, which was directed upwards, he passed a long tube over it and left the tube *in situ*. Then with a pair of straight forceps passed through this tube he was able to draw the pin into the tube and remove it.

Development of Secondary Nodules in Suture Scars After Operations for the Removal of Cancer.—A note on this topic is contributed by C. W. Mansell Moullin. He records the case of a man of 48 years in whom cancer had supervened on an old gastric ulcer. At operation a tight stricture of the pylorus was found with some disseminated nodules scattered over the serous surface of the stomach. Posterior transmesocolic gastroenterostomy was done and recovery was uneventful. When seen six months later, he was much better, so far as pain was concerned, and was considerably stouter, but there was a double row of cancer nodules on either side of the laparotomy wound. Two sets of sutures had been inserted: one, of stout catgut, interrupted, passing through all the layers of the abdominal wall except the skin; the other, of finer catgut, continuous, through the skin only. Practically all the suture points of the former series were infected; none of the latter. It was evident that cancer cells from the peritoneal cavity had invaded the wall wherever the parietal peritoneum had been pierced by a suture. The sutures had not carried the cancer germs in, for they had never been near the growth; but either by perforating the serous layer or by acting as irritants they had helped the development of the invading germs to such an extent that each point had become a cancer nodule. The immediate source of infection was in all probability the nodules noted on the serous coat of the stomach, which were constantly rubbing against the anterior abdominal wall. The line of the laparotomy incision itself seemed to be intact between the two rows of nodules. The same explanation, it seems to the author, is the more rational one in those cases in which cancer recurs at the suture points after operations for mammary carcinoma. It is not that the cancer germs are carried in by the needle or suture mechanically at the time of the operation and left to grow in the puncture made, but that they are more widely distributed in the surrounding tissue interstices than is apparent at the time, and only develop, or perhaps develop first, at those points where the resistance of the tissues is lowered by the presence of an irritant such as a suture.

The Value of Cytodiagnosis in Clinical Medicine.—Special points referred to by J. E. H. Sawyer are predominancy of small lymphocytes, and of polymorphonuclear cells, predominancy of epithelial cells, and effusions due to malignant effusions. Concerning cell counts in general, the author declares that it is necessary to obtain the fluid as soon as possible after it has been removed from the body. After a few hours the cells begin to degenerate and become in consequence very much more difficult to recognize. Some of the fluid should be centrifugalized gently and then the fluid poured off and a film made of the sediment. Care should be taken not to centrifugalize too long or too forcibly or otherwise many of the cells will be destroyed. It is much better to centrifugalize the fluid than to let it stand in a conical jar and then examine the sediment, for the cells degenerate very rapidly. After a film has been made it can be stained at leisure. The two stains found most useful are Leishman's and Jenner's. The differential count should be made under the one-twelfth oil immersion lens and to get an accurate percentage of the cells 500 should be counted. In many instances, however, and especially in cerebrospinal fluid of which only a small quantity can often be obtained, it is impossible to count so many on account of the scarcity of the cells. The differences in the percentages of the cells to each other in the various pathological conditions are often so great that usually such a large number of cells need not be counted. General conclusions are as follows: (1) Effusions of tuberculous origin contain a large percentage of small lymphocytes, ranging from 59 to 100 per cent.; (2) effusions of acute inflammatory origin, a large percentage of polymorphonuclear cells, ranging from 64 to 97 per cent.; (3) mechanical effusions contain chiefly endothelial cells, the highest count in the author's series being 98.8 per cent.; (4) effusions due to malignant disease can rarely be diagnosticated by count methods alone, but when such a condition is suspected to be present, the predominance of endothelial cells would greatly support that view.

The Unequal Distribution of Filariasis in the Tropics.—G. C. Low describes the researches he has made in the direction suggested by the title of his paper, which must be read in the original by those interested. The intermediate host of the filaria is a suitable mosquito (*e.g. Culex fatigans*), but it is difficult to understand, says the author, why a disease should remain localized to certain parts of the world although its intermediate host is much more widely distributed.

British Medical Journal, February 1, 1908.

The Critical Solution Point of Urine.—W. G. Atkins says that the most exact method of determining the efficiency of the kidney as an excretory organ is the determination of the total solid content of the urine as shown by the depression of its freezing point below that of pure water. The time hitherto required in making this test has been almost prohibitive for the examination of single specimens. The author has devised a new method which is freely described in his paper but the details of which cannot be given here. He concludes that the examination of urine by this method of the critical solution point method gives a reliable measure of the functional activity of the kidney producing it, and may be employed in all cases where cryoscopy can be. The difficulty of obtaining a clear solution with blood or blood serum has so far prevented the application of this method to their examination. The rise in critical solution point should not be less than 8° C. for the urine from a healthy kidney; ordinarily the rise is from 11° to 16° C. Each determination can be made in ten minutes, without weighing and without any special or costly apparatus. Only a small quantity of urine is required, not more than 5 c.c. for each determination; when specimens have to be collected by catheterization of the ureters this is a saving of time and occasions less inconvenience.

Inherited Syphilis.—A general consideration of this subject is given by R. C. Lucas, who discusses the effects of the specific virus on the various bodily organs. He believes that the mode of transmission is invariably through a syphilized mother. To his mind inheritance from the father alone is put entirely out of court. How, he asks, can a spirochete which is highly motile and whose length averages rather more than the diameter of a blood corpuscle penetrate an ovum 1-200 of an inch in diameter and multiply without destroying it? It would seem that when virulent the spirochetes penetrate the chorion or

placenta and occasion miscarriages, macerated fetuses, or premature births; but when the virus is attenuated by time or treatment the placenta forms a complete protection to the developing fetus, and it is the separation of the placenta at birth which allows the infection to take place through the umbilical vein. Hence the regularity of the secondary exanthematous stage from a fortnight to three months after birth. In these cases the separation of the placenta is the first stage and corresponds to the chancre of acquired syphilis. The author states that the milk of a syphilitic woman when received into the alimentary tract of an infant need not convey infection to a child. He also calls attention to the need of criticism in diagnosis. He says that every deformity, from dislocated hip to cleft palate, all defects such as hernia, infantile paralysis of various kinds and even nevi, have been described by various writers as dependent on inherited syphilis, and as if better to cover the anomalies the term "parasyphilis" has been invented to add to the confusion. Such generalizations he regards as crude and misleading. He does not deny that persons whose constitutions have been weakened by disease are liable to produce degenerates in succeeding generations; but in future the most certain test of the disease being syphilis will be the presence of the *Spirochæta pallida* in the part affected. This organism has an extraordinary persistency, producing local symptoms after lengthened periods, but happily we have in mercury and the iodides drugs which control its development and bring about its destruction.

Berliner klinische Wochenschift, January 27, 1908.

Extraperitoneal Cesarean Section.— Fromme says that while abdominal cesarean section under ideal conditions should have no mortality whatever, in practical work this result cannot be attained. Owing to previous attempts at delivery, repeated examinations, etc., the uterus is likely to be infected and then cesarean section is attended with considerable risk owing to the danger of peritonitis induced by the uterine germs. Frank has recently described a method of abdominal cesarean section which is performed extraperitoneally. The incision is a transverse one close above the symphysis and the peritoneum overlying the uterus is pushed back, a procedure which is readily possible if labor has already begun, as in that case the attachments between the membrane and the organ are very lax. Frank's technique is to suture the visceral and parietal layers of the peritoneum together in order to shut off the abdominal cavity and then to open the uterus through a transverse incision, but Fromme finds that it is possible to gain sufficient room to make a longitudinal incision and considers that this is much preferable, as a transverse uterine scar is more likely to give trouble in future pregnancies. The drainage of the abdominal wound advocated by Frank is also undesirable and vaginal drainage is sufficient. Fromme has operated on four patients by this method, all of whom when brought into the clinic were in such a condition as to have rendered the usual cesarean section very dangerous. Three of the patients did well, but the fourth died of eclampsia on the next day and at the autopsy it was found that there was a beginning peritonitis about the uterus.

Münchener medizinische Wochenschrift, January 14, 21, and 28, 1908.

The Effect of Electrical Stimuli on the Distribution of Blood in the Human Body.—Geissler describes a series of experiments undertaken to determine the effect of electrical currents on the distribution of the blood. One arm of the subject was placed in a plethysmograph which was provided with an index that recorded its excursions on a kymograph. One electrode was connected with the water in the plethysmograph and the other was applied either to the back of the neck or to the other extremities. Numerous precautions are necessary in carrying out these experiments and are detailed by the author. As the result of a considerable number of observations it was found that electrical stimuli produce a decrease in volume of the blood-vessels. This effect is produced both by galvanic and by faradic currents and there is no difference in regard to the anode or cathode. Subject to individual variations the degree of the decrease in volume depends on the strength of the current. Observations were also made on the blood pressure and pulse rate. It was found that in general both the galvanic and faradic currents gave rise to an increase in blood pressure which once reached 14 mm. but was usually between 5 and 10 mm. The rise did not always correspond to the strength of the current. The behavior of the pulse was irregular, sometimes increasing, sometimes diminishing in frequency. The author believes that these experiments indicate that the heart and blood-vessels are susceptible to influence by electrical stimuli and that this may be made use of practically.

The Ophthalmoreaction in Tuberculosis.—Blum and Schlippe as the result of a considerable number of observations, some of which were controlled by autopsy and others by the injection of tuberculin, come to the conclusion that the reaction very frequently indicates correctly the presence or absence of tuberculous disease. A negative reaction does not exclude tuberculosis and it is also possible that further autopsies may show that it may be positive in nontuberculous subjects under certain exceptional circumstances. Furthermore it must be borne in mind that while the reaction indicates the presence of tuberculous disease, this does not prove that the illness in the course of which the reaction is performed is necessarily of tuberculous nature. In another article in the same number Schröder and Kaufman in addition to reporting their own observations, present a summary of the cases so far published in which this reaction has been used. The total number of cases is 1,882. Of this number 971 were in tuberculous individuals, and the reaction was negative in 11.5 per cent.; in 284 suspected cases the reaction was negative in 48.6 per cent.; in 627 nontuberculous cases it was negative in 87.3 per cent. The authors consider that it is not quite so reliable as the injection of tuberculin, but they believe that it is less often positive than the latter in individuals having small encapsulated foci in glands or at the apices of the lungs, and that this may to some extent explain the disparity in the results obtained by the two methods. They regard the ophthalmo reaction as practically harmless if dilute solutions are used and prefer it to the subcutaneous injection on this account as well as owing to its convenience.

Eighty Lumbar Anesthesias Without Failure.—Holzbach considers that this method does not deserve the criticisms that have been directed at it and describes the technique now in use at Sellheim's clinic, by means of which the last eighty cases have been anesthetized without misadventure. An hour and a half and again half an hour before the beginning of the operation the patients are given an injection of .01 g. of morphine and .0001 g. of scopolamine. The needle is introduced between the second and third lumbar vertebrae in the midline with the patient sitting up in bed. An important point is to prevent the motion of the needle that is likely to be communicated to it during the injection if it is connected directly to the syringe. To avoid this a piece of rubber tubing should be interposed. The anesthetic used is stovain, .04 to .08 g. with .0001 to .0002 g. of adrenalin, the two not being mixed until just before the injection. The patient is kept upright for five minutes and is then slowly and carefully allowed to lie back against the pillows with the trunk elevated. In the transfer to the operating table care is again taken to keep the head elevated. The Trendelenburg position is used, though the patient is allowed to assume it only very gradually. The theory is that as the anesthetic is lighter than the cerebrospinal fluid it will float on top of this if the change in position is effected slowly. The anesthesia usually lasted sixty minutes and in fourteen cases the operation had to be completed under ether, though only a very small amount of the latter was necessary.

Pentoses in the Feces, and Their Quantitative Determination.—Jolles says that although the urine has been studied from the standpoint of its possible pentose content the feces have received little attention in this regard. He reports the results of a series of observations made on a patient with pentosuria, who excreted from 25 per cent. to 38 per cent. of pentose, amounting to four or five g. a day. Jolles describes a method for the qualitative determination of pentose in the feces and another for the quantitative estimation. It was found that this patient excreted 4.7 per cent. of pentose in the feces (dried), while a normal individual excreted only .14 per cent. to .26 per cent. In order to test the effect of diet, both of these persons were put for three days on a regimen almost entirely free from vegetables, with the result that the feces of the patient contained 4.53 per cent. of pentose, while those of the normal person had only traces too small to estimate quantitatively. A preponderatingly vegetable diet was then given to both during three days, with a result that the patient excreted 6.71 per cent. and the normal person .59 per cent. in the feces. The nature of the pentose was not determined. The author recommends that systematic quantitative determinations of this sort be made in hospitals where the necessary facilities are available.

Vaginal Operation vs. Laparotomy.—Lehmann reviews the comparative merits of these two methods of operation, greatly to the advantage of the vaginal route. In spite of the progress that has been made in the methods of suture and in incisions, such as the transverse incisions of Küstner and Pfannenstiel, the danger of hernia and the deformity of a visible scar still remain. A number of the most prominent gynecologists now perform more than 80 per cent. of their operations through the vagina, and Leh-

mann adopts the view that laparotomy should be performed only when vaginal operation is contraindicated. The contraindications are, however, only malignant new growths or the suspicion of such, and tumors whose growth is principally lateral. Solid tumors such as myomas if they are not too broad may be removed by the vagina even if they reach to the umbilicus. In such cases they are cut into small portions and removed by morcellement. Non-malignant cystic tumors can readily be removed from below even if they reach to the costal border and occasion severe dyspnea through pressure on the diaphragm. Of the operations for retroversion of the uterus the author prefers vaginifixation, and he also speaks highly of vaginal cesarean section as a means of rapid delivery when the pelvic measurements are normal. He admits, however, that in every case of vaginal operation everything should be prepared for a laparotomy should this be necessary.

Meat Poisoning and the Widal Reaction.—Liefmann says that while it has been recognized that in very rare instances typhoid fever may exist without a Widal reaction being obtainable, it is also true that a positive Widal may be present in an acute illness other than typhoid fever. An instance of this kind occurred in a garrison of which fifty soldiers as well as twelve inmates of a neighboring home for the indigent within the space of a few days developed an acute illness which at first was taken for influenza, but on the appearance of diarrheal symptoms was diagnosed as due to food poisoning. These patients all gave a positive Widal reaction and from the stools of some of them a Gärtner bacillus was isolated. The serum also reacted with this organism, but not in as high dilutions as with the typhoid bacillus. The meat supply was suspected and it was found that at the time when the cases of illness occurred both the garrison and the home had been supplied with the same mixture of chopped meats from a single butcher. One of his clerks was somewhat indisposed at this time and it was discovered that his serum, as well as that of another clerk who complained of no symptoms, also agglutinated the typhoid bacillus. The author concludes that when the Widal reaction is performed in a laboratory the examiner should be supplied with a brief clinical history of the case, as in the present instances in which the agglutination was positive in dilutions of 1-50, 1-100, and in many cases much higher, a laboratory diagnosis of typhoid would have seemed justified.

Deutsche medizinische Wochenschrift, January 9 and 16, 1908.

The Ophthalmo-Reaction in Tuberculosis.—Schenck says that while as yet it has not been determined for this method what is the minimum dose which on yielding a negative result enables it to be said definitely that the subject in question is not tuberculous, for routine use it is wiser to use only two drops of a ½ per cent. tuberculin dilution. It is important that this be freshly prepared. It is not a sufficiently large dose for all cases, but still is the most advisable for regular use. It is also extremely important to inspect the eyes carefully for any possible differences that may exist between them and also to detect any inflammatory conditions, which always contraindicate the ophthalmo reaction. The advantages of the method over the injection reaction are that it is simpler, less dangerous, and may be applied in febrile cases. The reaction was positive in every one of eight tuberculous patients tested, in 48.3 per cent. of 29 patients suspected of tuberculosis, and in 14.28 per cent. of 63 unsuspected cases. In 30 cases in which tuberculin was injected as a control the two reactions were the same in 25 instances. The general reaction to tuberculin injection after the ocular reaction has subsided causes the latter to reappear again. If the ocular reaction is positive the probability of the existence of tuberculosis is very great, but if the result is negative while there is good clinical evidence of the disease, the finding should be controlled by a tuberculin injection. The fact that it sometimes cannot be obtained in advanced cases does not militate against its value, since the diagnosis is not in question under these conditions.

Functional Diagnosis in Intestinal Disease.—Aldor says that high irrigation with diluted Carlsbad water is an effective means of treating chronic intestinal catarrhs, while the action of drugs is more or less symptomatic. Successful dietetic treatment of these conditions depends on an exact functional diagnosis. When such cases are carefully studied it will be found that in many instances chronic intestinal catarrh is accompanied by disturbances of gastric function, which form a useful field for therapeutic measures. In diarrhea accompanied by achylia hydrochloric acid is a valuable remedy. Investigation of intestinal function by means of Schmidt's diet is of much service, but the administration of raw meat as part of the test is superfluous. The formation of gas, and alkaline reaction in the feces indicate increased proteid putrefaction, if accompanied by acid reaction, carbohydrate fermentation. If the former condition is plainly evident it is safe to assume that the entire intestinal tract is involved. Functional examination of the intestinal tract is useful in determining what types of food are the most suitable in the case under consideration. If the meat test is positive, the proteids are cut down, and the carbohydrates when the fermentation test is positive. Gelatin is an ideal food for patients who are unable to take albumin on account of a positive meat test.

The Treatment of Injuries of the Liver.—Neumann describes twenty-two cases of injuries of the liver of various sorts which were treated surgically. Two of the number were stab wounds, six gunshot injuries, and fourteen ruptures of the organ were due to blunt violence. In seventeen cases there were serious injuries to other viscera besides the liver. Both of the stab wound patients, four of the gunshot patients, and four of those with ruptures of the liver recovered. The author is in favor of prompt laparotomy in both stab and gunshot wounds in which there is an injury which it is suspected may involve the abdominal cavity. Even if there is only a probability of this, opening the abdomen is indicated, and any wound apparently involving only the abdominal wall should be laid open freely in order to determine whether or not it is a perforating one. In twenty-one cases in which the patients were admitted soon after the injury there was no noteworthy abdominal distention, and observation in accordance with Heineke's statement that early meteorism by itself speaks against rather than for a serious injury In dealing with ruptures of the liver prompt operation is often wonderfully effective, and three of the author's recovered cases were instances of very severe trauma. For controlling the hemorrhage he prefers packing to suture, but states that in order to be effective large amounts of gauze must be used. In one instance eleven and one-third meters of gauze bandage 20 cm. wide were introduced for this purpose. Portions of liver tissue partly sequestrated and whose future nutrition seems doubtful should be resected; thus, in one of the author's cases followed by recovery the entire left lobe was removed.

The Conjunctival Tuberculin Reaction.—Levi says that this term is preferable to the ordinarily used one of ophthalmo-reaction. He tested the measure in forty-one cases of demonstrated tuberculosis with 85 per cent. of positive results, the six negative patients being very far advanced and cachectic. In fifty-four suspicious cases 40 per cent. of positive results were obtained, the method apparently being a little less delicate than the hypodermic injection of tuberculin. Two hundred and thirty-five individuals either entirely healthy or showing no signs of tuberculosis were also tested. Of this number six, or 2.5 per cent., gave a positive reaction. Two of these also gave a positive result on the hypodermic injection of tuberculin. One of the patients dying of diabetes, at the autopsy showed no evidences of tuberculosis. The author thinks favorably of the method on account of its convenience, but states that a positive reaction does not always indicate tuberculosis, especially not in typhoid fever patients, while negative results do not certainly preclude the disease, particularly in anemic and cachectic persons. Owing to the hypersensitiveness which appears in 75 per cent. of nontuberculous individuals the same eye should not be used a second time in case the first application has been negative.

Treatment of Carbuncles.—Reissman gives the following advice: Do not abort a carbuncle by injection; do not poultice; do not cut, unless there is a very serious and extensive involvement of the adjacent tissues. The Bier hyperemia gives excellent results and is helpful in alleviating the pain. The general plan of treatment, while, of course, modified to suit individual cases, is this: If the inflammation has attained quite considerable proportions with a good deal of induration and no opening or outlet, I make a small incision about a quarter inch in length under local ethyl chloride anesthesia and then apply a cup large enough to extend a little beyond the external margin of the swelling. This cup is left in place from ten to twenty minutes at each sitting. On removal of the cup the surface is cleansed and a plain wet dressing is applied. This treatment carried out for five to six days will in nearly all cases effect a cure which has been painless from the beginning and has left the patient free from discomfort all the time. A serviceable cup may be devised with a glass, a piece of cotton and a match.—*Medical Times.*

Book Reviews.

Bilharziosis. By Frank Cole Madden, M.D. Melb., F.R.C.S. Eng.; Professor of Surgery, Egyptian Government School of Medicine; Senior Surgeon Kasr-el-Ainy Hospital, Cairo. Illustrated. New York: William Wood and Company, 1907.

Many more cases of bilharziosis are now seen in the United States than in the past decade, owing largely to the increased immigration from the islands of the West Indies, where there are a number of endemic foci of infection, so that physicians, especially those of the Atlantic coast, are not infrequently meeting with more or less advanced cases of this disease. It is not unlikely that some of the workers returning from the Panama Canal Zone may have become infested with this parasite, and may spread it in this country. It is, therefore, most timely and important that a monograph of this scope should be placed within the reach of the American practitioner. The volume is most excellent in every regard. The illustrations, almost all of which are from photographs, give a very complete picture of the parasite and the lesions produced by it. The writer holds the theory of invasion proposed by Looss, that the ciliated embryos or miracidia penetrate the skin, and finding their way to the liver there pass through a sporocystic stage, the young worms of both sexes developing and appearing in the veins of the liver, and by the portal circulation finally invading the mucous membranes of the intestine and bladder. In both these situations they give rise to hyperplastic new growths and extensive ulcerations. The diagnosis is made by finding the ova either in the stools or in the urine. The symptoms and treatment of the disease are very fully given. The present volume may, therefore, be considered a very valuable addition to our knowledge of this important tropical disease, especially for those who cannot consult the German publications on the subject, particularly those of Professor Loos, which have appeared in a very complete form in Mense's Handbuch der Tropenkrankheiten.

Introduction à la Psychiatrie Clinique. Par le Professeur Emile Kraepelin, professeur de psychiatrie à l'Université de Munich. Traduite sur la Seconde Edition Allemande, par MM. Albert Devaux et Prosper Merklen. Préface de M. le Docteur Dupré, professeur agrégé à la Faculté de Médecine de Paris, médecin des hôpitaux et de l'Infirmerie spéciale de la Préfecture de Police. Paris: Vigot Frères, 1907.

Kraepelin is without doubt the most distinguished psychiater of recent times. It does not, therefore, excite surprise that his writings are translated from the German into the other modern tongues. This French translation of the second edition of his Introduction to Clinical Psychiatry is a literal translation and well done. The second edition contains two additional lectures and a number of corrections of the original text, especially alterations in the diagnoses of some of the numerous cases used as illustrative examples in the lectures. The frankness with which the author makes these alterations indicates his innate desire for accuracy; and the careful descriptions of the cases reflect the free interchange of opinion and discussion between the master and his assistants which is conducive to the best work and for which Kraepelin is peculiarly noted. Theoretical discussions are practically eliminated. Cardinal signs and symptoms are emphasized for diagnosis. Several chapters are devoted to dementia præcox in which Kraepelin finds some general analogy with dementia paralytica. There are many things in this work which are at variance with expressed French psychiatry, but such books as this and de Fursac's Manual (based on Kraepelin's writings) are calculated to do no harm at least to the somewhat conservative French school. The title is misleading. Many buy the original or the English translation under the impression that it is Kraepelin's textbook; whereas it is chiefly a description of cases. Could not this confusion be prevented by entitling the work "Clinical Lectures on Psychiatry?"

A System of Medicine by Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College; and Humphrey Davy Rolleston, M.A., M.D., F.R.C.P., Physician to St. George's Hospital and to the Victoria Hospital for Children; Sometime Fellow of St. John's College, Cambridge. Volume III. London: Macmillan and Co.; New York: The Macmillan Company, 1907.

In this volume of the new edition of Allbutt's system are considered the "diseases of obscure origin," among which are included the rheumatoid affections, rickets, osteomalacia, diabetes, gout, and a number of minor affections. This part of the book constitutes a new work rather than a revision, for some of the more important articles, such as rheumatoid arthritis, have been entirely rewritten, and new articles, such as achondroplasia and pulmonary osteoarthropathy, have been added. The article by Garrod on rheumatoid arthritis and osteoarthritis, or arthritis deformans, is an excellent presentation of conditions well grouped among those of obscure origin. The author questions whether the affections so named constitute a definite morbid entity; he makes a definite distinction between rheumatoid arthritis and arthritis deformans, and is inclined to regard even rheumatoid arthritis as a group of arthritides of varying causation, though there is a form occurring in adults the features of which are so uniform as to make it probable that they do constitute a morbid entity. It cannot be affirmed that the author has yet solved the problem of the chronic arthritides, but his article throws a flood of new light on these diseases and may be said without fear of contradiction to be the best and clearest exposition of this difficult subject that has ever been written. The volume also treats of the diseases of the alimentary canal and of the peritoneum in a series of twenty-seven articles by many of the best known British writers. The subject is well presented in these contributions, but there is little that is new or striking to attract the attention of a reviewer in search of novelties. Old subjects, however, may be presented in a new light, and this is the case with many of these, the hackneyed theme of constipation, for example, being set forth by Lauder Brunton in a peculiarly fresh and thought-provoking manner. The volume well sustains the reputation of this new edition of a capital treatise.

The Sexual Instinct, Its Use and Dangers as Affecting Heredity and Morals. Essentials to the Welfare of the Individual and the Future of the Race. By James Foster Scott, B.A. (Yale University), M.D., C.M. (Edinburgh University), Late Obstetrician to Columbia Hospital for Women, and Lying-in Asylum, Washington, D. C., etc. Second edition, revised and enlarged. New York: E. B. Treat and Company, 1908.

The first edition of this book was published about ten years ago, and was at once recognized as one of the very best works dealing with a difficult but important subject. The present edition differs but little from its predecessor; a few slight additions have been made to some of the chapters, and two new chapters have also been added. The chapter on Perversions has been dropped, as it was of little practical use to any except experts, and they will seek and find all that they want on this subject in the works of Kraft-Ebing, Havelock Ellis, and others. The volume differs from several others on the same subject, in that it cannot possibly do any harm. At the same time it is capable of accomplishing an immense amount of good; and physicians and parents will, alike, welcome a book which can be placed in the hands of those who most need the information and advice therein contained. There are no morbid and revolting case-histories or prurient and unnecessary details; but the book stands preeminent for its honesty and purity of purpose, its plainness of speech, and its manifest helpfulness to readers of every class.

The Skin Affections of Childhood, with Special Reference to those of More Common Occurrence and their Diagnosis and Treatment. By H. G. Adamson, M.D., Lond., M.R.C.P. Physician for Diseases of the Skin, Paddington Green Children's Hospital; Physician in Charge of the Skin Department (Formerly Physician), Northeastern Hospital for Children; Assistant in the Skin Department, Westminster Hospital, pp. 287. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, 1907.

It has been deemed wise by the author to write a special treatise on the skin diseases of childhood inasmuch as the extreme youth of the patients makes clinical differences in the grouping and distribution of the lesions and in the mode of treatment. He classifies his cutaneous manifestations under congenital affections, affections due mainly to direct physical causes, those due to parasites, those due to toxemias and microbic infections, those due to nervous and to unknown origin. This etiological classification is helpful in treatment, both prophylactic and curative. The lesions are well described, the author assuming that the reader knows the elementary divisions such as papules, pustules, bullæ, etc., and thereby saves time and space. The pathological processes could have been described more fully, but in a work of this size it is excusable when the diagnosis, gross lesions, general course, and treatment are so well given. Twelve excellent plates, some of them double, are very helpful and are well executed, and constitute a most desirable way of teaching dermatology.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held January 2, 1908.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Annual Reports.—The reading of these reports preceded the scientific session. The meeting was held under the auspices of the Section on Pediatrics, and was devoted to the topic, general tuberculosis in children.

The Pathology of Tuberculosis in Children.—Dr. JOHN MCCRAE of Montreal, Canada, read this paper. He said the first year of life was comparatively free from tuberculosis, although Schwer found 14 per cent. of his series of autopsies between the second and twelfth months tuberculous. The first three hemidecades were all liable, the first being perhaps most so, although Müller's figures were greatly in favor of the first. Of 11,000 indoor patients in hospitals in the cities of England, Scotland, and Ireland, 25 per cent. were tuberculous, and roughly half of these were being treated in the surgical wards. In children up to 15 years of age there were several groups of cases to be considered. First, the small class of those who in early infancy had intestinal tuberculosis from ingestion; second, those of any age who stored up the germs for a longer or shorter time, and, finally, suffered from an infection which was generalized; this showed itself in a variety of different forms; third, those few older children who developed phthisis. Tubercle bacilli, originally, were probably all of one kind; by lapse of time and difference of environment, strains had been developed, so that they now had human, bovine, avian, piscine, and reptilian forms; each of these was non-pathogenic for races other than its own host-race, save for those animals that were particularly susceptible to any form of tubercle bacilli. It was probably the case that the average human could overcome an infection of bovine bacilli more easily than that by human bacilli; nevertheless, it was certain that a number of bovine infections occurred. There was a type of infection in children which was called "bovine," viz., a slowly progressive tuberculosis, tending to much overgrowth and to dry cascation, which affected mainly lymph nodes anywhere in the body. Children were liable to infection by air-borne bacilli of the human, but less frequently of the bovine type. They could ingest human bacilli picked from the floor or from food carelessly exposed. They were liable to infection by ingestion of bovine bacilli from milk and other forms of food of which milk was a component part. The latter infection only was discussed. Milk and butter were likely to contain the tubercle bacillus, if the cows giving the milk had tuberculosis of the udder, and might contain it even if udder disease was not present; the bacilli in the milk supply depended then on the number of infected animals in the environs. Some people drank with impunity milk containing tubercle bacilli, but weakly children and those whose diet consisted largely or wholly of milk were apt to be infected. Of children under five years of age affected by tuberculosis, four-fifths were probably infected by air-borne human bacilli. One-fifth might show the bovine form, and this percentage decreased greatly as the age progressed. He said that the one who dogmatized least as to what nodes were primary and what secondary was most likely to be least in error. It must be admitted that bacilli could pass through tissues and glands without leaving traces visible to the eye, and could remain in tissues for considerable time without exciting even lesions so slight as to be recognizable only by the microscope. He gave his personal experience in a special class of infants, foundlings; these segregated children artificially fed on milk that was pasteurized were practically free from tuberculosis. In 747 autopsies, of which 60 per cent. were on children three months of age or less, tuberculosis was found but five times (0.66 per cent.). Of the five, one was three months, two five months, one fourteen months, and one was a baby of ten days, with tuberculous mesenteric glands and tuberculous ulcers of the ileum and cecum. He believed that the phenomenon of the disease manifesting itself in bone and joint and remaining there was some expression of the sum total of lowered bacterial virulence and heightened resistance of an individual tissue. He was not prepared to accept that such infections were necessarily bovine; he felt sure that the individual resistance was a greater factor than the bacterial variation of virulence in producing these cases of apparently a typical course. The concentration of the disease in lymph nodes might be but a mark of the tremendous fight the lymphatic tissue was making, and perhaps the universally tuberculous nodes were but another expression of a generalized miliary tuberculosis, but one that had been countered by a better resistance on the part of the child. He wished to show that meningeal tuberculosis in a large percentage of the cases was merely a local evidence of a generalized tuberculosis. At the Royal Victoria Hospital, the inmates of which were mostly children of fifteen or less, in 1,000 autopsies, they had 29 cases of tuberculous meningitis, with complete autopsy; 21 of these had a generalized tuberculosis of many organs. Two others had tuberculous foci elsewhere in the body. Thus, nearly 80 per cent. of the cases of tuberculous meningitis had a hopeless extension of the disease elsewhere.

Recent Diagnostic Methods.—Dr. W. H. PARK spoke on this subject. He said that he would limit his remarks to the recently proposed skin and eye inoculations. But, before touching upon technique, he thought it best to speak of the meaning of the reaction following inoculation. If one took an animal, a guinea pig, for instance, and injected a minute quantity of serum into it, that animal after ten days would be sensitized, so that if a fairly large quantity of serum was injected the animal would die in convulsions; whereas if the same dose of the serum was given to a guinea pig not so sensitized, results would be absolutely harmless. It was also found that egg white would sensitize such an animal. It was further found that other proteids, as well as bacterial proteids, would in the same way sensitize animals. Thus, if guinea pigs or rabbits or even men were injected with dead tubercle bacilli they would after ten days be sensitized. This sensitization would last for a considerable length of time, for months or longer periods, until the newly formed substance was eliminated from the body. The important point was that a minute quantity of suitable proteid would thoroughly sensitize an animal or man to similar proteids, and this sensitization would continue for months or even years. Larger quantities did not experimentally sensitize much more than a minute quantity. When one got a reaction from the subcutaneous injection of tubercles, it was not a reaction because of the presence of tubercle poison in the body, but because of the formation of antibodies due to the body having reacted to the tuberculosis infection. Therefore, if the body ceased to produce these protective substances, the poison in the tissues adjacent to the disease and in the circulation would not be neutralized, and no tuberculin reaction would occur. These reactions were not reactions to bacterial poison, but to the body products produced in response to the poison. In advanced cases, therefore, reactions would frequently not occur. Dr. Park said that all knew, no doubt, the old method of injecting subcutaneously minute quantities of Koch's original tuberculin, using 1-1,000 dilution, and giving from one to five c.c. subcutaneously and increasing the dose. This was the old method and this gave a temperature curve and slight local disturbances at the seat of disease. This summer von Pirquet, Wolff-Eissner, and Calmette had brought out new methods. When von Pirquet was working with serum

sickness and studying the reaction of vaccination with cowpox in immunized persons, he was led to try placing tuberculin upon the abraded skin, using 1-4 strength, one drop of which was rubbed into the abraded skin. He found that in tuberculous cases he got a typical reaction. Von Pirquet usually took an arm and made a little vaccination mark by rotating the point of the vaccine blade against the skin until a little abrasion was made. That would be the control spot. Then two other vaccinations or scarifications were made and into them was rubbed a 25 per cent. solution of Koch's tuberculin. The tuberculin could also be applied as in ordinary vaccination to an abrasion made by a needle. In the course of eight, twelve, or twenty-four hours appeared a papular swelling and redness the size of a dime or even a twenty-five cent piece. So, by contrasting the reaction of the two scarifications with tuberculin with that without the tuberculin, one could judge the difference between the very slight inflammatory reaction due to the abrasion and that due to tuberculin. Dr. Park had seen something over 20 positive cases of this kind, and in most of them the reaction was quite striking. In about 33 per cent. there was a rise in the temperature of from one to one and a half degrees along with the reaction. In the cases he had seen the inoculation never gave rise to other noticeable constitutional disturbances. Wolff-Eissner believed that he might get the same reaction without the use of this scarification by applying it to the conjunctiva, and he tried using a 1 to 10 dilution, placing one drop of it on the lower eyelid. This gave a marked reaction. He did not try a much weaker solution. Calmette, in order to avoid such a marked reaction or any nonspecific irritation, tried the method of purifying the tuberculin by precipitating the toxins in a 65 per cent. alcohol. The precipitate was washed, dried, and a 1 per cent. solution of it made in water. This 1 per cent. solution was then used as in the Wolff-Eissner method. An important point was to note carefully the condition of the two eyes before the inoculation, because one eye might be previously congested. The reaction might develop in from six to thirty-six hours. If one could only examine once it should be after twenty-four hours. It was very important in following up these new methods to note carefully the amount of reaction that occurred.

The method of application was as follows: Two solutions were employed in diagnosis, which contained 0.5 per cent. (No. 1) and 1 per cent. (No. 2), respectively, and which might be used successively in each eye if time permitted. In this way unnecessarily severe reactions might be avoided. The eyelid should be held down until the drop was distributed about the sac without overflowing on the cheek. The same eye should not be used for a second test, as it appeared to become sensitized to a certain degree by one test. The tested eye should be kept from external irritation by rubbing, wind, dust, and smoke. The first sign of a reaction appeared in from three to twelve hours in most cases, but might be delayed twenty-four and even forty-eight hours, and continue for a week. The presence of a reaction was indicated by a scratchy feeling, secretion, and redness of the inner canthus. The following scheme was proposed for recording the degree of reaction: Negative, no difference in color when the lower eyelid was pulled down. Doubtful, slight difference with redness of caruncle. + = distinct palpebral redness with secretion. + + = ocular and palpebral redness with secretion well marked. + + + = deep injection of entire conjunctiva with edema of lids and photophobia, and secretion. Contraindications: Any existing disease of the eye or lids, conjunctiva, blepharitis, trachoma, keratitis, and iritis. Eyestrain from errors of refraction need not prevent the use of the test so far as had been observed.

The objections to the test were slight. In a few the reaction, when very marked, might last for several days, or even a week or two, but no permanent ill effects had remained. Dr. Cutler in nearly 200 cases had not seen any bad effects in the use of the tuberculin in this way. Dr. Park had seen over one hundred cases and in none were there any disagreeable effects nor were there left any bad effects whatever. Dr. Park said it was as yet too early to try to estimate the exact value of either the skin or the eye reactions. Most considered that the skin reaction was little less apt to occur than the eye reaction. In young children the reaction was believed to indicate an active focus of tuberculosis, while in older children the reaction became less definite, as it might mean either a present or recently healed infection. In the adult the reaction was present in such a large percentage of the cases that it was hard to know whether there was an active or latent tuberculosis, or whether the bacilli had simply been absorbed, giving no reaction whatever except sensitizing the individual. Negative results were always helpful in excluding absorbed tubercle bacilli, latent or active tuberculosis. Dr. Park said that he had notes of the first cases which he tested in cooperation with Dr. Huddleston, which illustrated the difference between the two tests. First there were the tuberculin tests at North Brothers Island. There were four adults believed to have tuberculosis: the eye test was positive in three, doubtful in one. The vaccination test was positive in three and negative in the same one in which the eye test was doubtful. The doubtful case was in a lad eighteen years old, and the process involved two-thirds of the left side, was quiescent, and without any elevation of temperature. The control cases were three children who were convalescing from scarlet fever. The eye test and vaccination test were negative in two. The eye test and vaccination test were positive in one; the mother of this patient died of consumption.

The tests at Gouverneur Hospital on twelve children, all living in families with a case of tuberculosis, showed the eye test was positive in five, doubtful in three, and negative in four. The cutaneous test made on ten was positive in four, doubtful in two, and negative in four. Of these cases in one the eye test was doubtful, the vaccination test was negative, while in another the eye test was negative and the vaccination test was doubtful. In a third case both tests were doubtful.

While both these methods could be so readily employed, it should be borne in mind that sometimes patients became unduly alarmed, since they interpreted a positive reaction to mean an active and advancing tuberculosis, when, as clearly noted, it might mean nothing but a recently healed point of infection. Very anemic persons, as well as those in an advanced or dying condition, frequently did not react. The precipitated tuberculin for use in the eye was at least fairly stable, and could be kept for a number of weeks; the tuberculin for the skin was good for at least six months.

Laboratory Aids to the Diagnosis of Tuberculosis in Infants and Children.—Dr. T. Homer Coffin read this paper. He said that tuberculous affections in children often ran an obscure course and his paper was intended to emphasize those aids which were to be found in the laboratory. The microscopical examination of the blood usually showed a marked diminution in the hemoglobin and number of red blood cells. There might be a leucocytosis if the process was associated with suppuration. As Cabot had already stated, there was a functional debility of the blood through lack of nutritive substances in the plasma. In tuberculous meningitis the blood count was about normal, while in other forms a leucocytosis was found. Tubercle bacilli had been demonstrated in the blood. It had been stated by some authors that the tubercle bacilli might be demonstrated in the urine when the tuberculous process was elsewhere than in the urogeni-

tal tract, but in such cases they occurred, if at all, in very small numbers. In examining urine for tubercle bacilli one should guard against mistaking for them the smegma bacillus. In examination of the sputum Findlay's method was employed, *i.e.* the stomach tube, inversion of the child during a paroxysm of coughing, or expectorant mixtures might be employed. In older children the examination of the sputum often revealed the presence of the bacilli. With regard to the examination of the fluids of the body, he said the predominating type of cell was more indicative of the stage and severity of the disease than its etiology. The cerebrospinal fluid in tuberculous meningitis often showed the presence of the bacilli. Holt had found them present in every one of forty-two cases. The examination of the feces made many very sanguine regarding the diagnosis of tuberculosis.

This was particularly so because children swallowed their sputa. In tuberculosis of the intestines, associated with diarrhea, blood, and mucus, the bacilli were usually found after careful search. Examinations of the secretions of the eye, ear, nose, throat, etc., were of value. In various portions of the body, such as the throat, nose, tonsils, etc., if the microscopical examination of the secretions was negative, portions of the tissues might be excised and hardened, and the examination of sections might reveal the presence of tuberculosis.

Channels of Communication; Their Relative Significance.—Dr. S. McC. Hamill of Philadelphia read this paper. He said the avenues by which the tubercle bacillus got into the human body were the maternal circulation (congenital tuberculosis), the skin, the ear, the conjunctiva, the urogenital, the respiratory, and the intestinal tracts. It had been advocated by Baumgarten and his pupils that the majority of the cases of tuberculosis were of congenital origin. There was no doubt, however, that the vast majority of tuberculous subjects got their infection through the respiratory and alimentary tracts, and it was regarding the relative frequency of these two modes of infection that there existed such a wide difference of opinion. The evidence at hand led them to believe that fetal infection, as compared with other forms, was exceedingly rare. The frequency with which the tubercle bacillus found its way through the skin to the body was extremely difficult to determine, but it was generally thought that this mode of infection was uncommon. The other avenues of infection, through the conjunctiva, the ears, and the urogenital tract, were less frequent but well established. In the vast majority of tuberculous subjects infection occurred through the respiratory or alimentary tract. In the light of facts he presented it was manifest that one could not safely determine the portals of entry of the tubercle bacillus from the appearance of lesions found at autopsy. They were compelled, therefore, to turn to the results of animal experimentation. The experimental results bearing on inhalation tuberculosis which were most deserving of consideration in detail were those of Flügge. He produced pulmonary tuberculosis by inhalation in guinea pigs, rabbits, calves, and dogs, by means of a very small number of tubercle bacilli; in guinea pigs with less than fifty. The bacilli were floated in air in the shape of droplets. He concluded from these experiments as follows: 1. That inhalation represented a mode of infection as efficacious as subcutaneous injection, with regard to the very small dose required, and that inhalation infection produced a disease more rapid in course than did subcutaneous injection. 2. That it might be accepted as proven by the inoculation of the peripheral parts of the lung into guinea pigs immediately after exposure to an atmosphere containing droplets that at least some of the bacilli inhaled with the air in the shape of droplets were carried to the finest bronchi. 3. That the quantity of bacilli required to produce manifest symptoms of disease, when ingested with the food, was millions of times larger than when infection was by inhalation, and the fatal termination took place at a much later period. He accepted it as proven, therefore, that inhaled tubercle bacilli were capable of producing tuberculosis directly, and not, as some authorities asserted, because some of them were swallowed and penetrated into the body from the intestines or throat. These observations of Flugge required confirmation. His claim that the floating of bacilli-infected droplets in the air was more dangerous than the bacilli-laden dust was not in accordance with the results of other investigators, and this view was directly opposed to clinical experience. It would make living with a tuberculous patient dangerous, not so much from the particles of dried sputum attached to a dirty patient as from the droplets coughed up by them. This would make the nursing of tuberculous patients in sanatoria and hospitals a particularly dangerous occupation. Practical experience entirely disproved this, since cases of infection among nurses were almost unknown. The work of Bartel and Spieler would seem to indicate that the intestinal tract was the most common avenue of infection. These authors admitted the possibility of infection by both the alimentary and intestinal tracts. The tonsillar mode of infection had been advocated by many as a common, if not the most common, mode of infection. Grober had taken the attitude that the lungs might be directly infected through the tonsils and that the frequent involvement of the apex of the lung was explained by this mode of infection. He supported this view by the results of experimental work done on dogs, in which he injected into the tonsils some Chinese ink in suspension. A considerable quantity of this ink was found in the glands directly above the costal pleura at the dome of the pleural cavity and in the efferent glands. As the apex of the lung was in direct contact with this portion of the costal pleura, it was easy to understand why granules were also found in the pleura covering the apex. Infection through the medium of the intestinal tract had obtained a great deal of support in recent years. Calmette, Guerin and Delearde, in an article on the intestinal origin of tuberculous tracheobronchial adenopathy, reached the following conclusions: 1. That experimentally in animals and clinically in infants every time a tuberculous infection occurred in the tracheobronchial glands tubercle bacilli existed in the mesenteric glands even if they seemed healthy. 2. If the infection of the mesenteric glands preceded the appearance of the tracheobronchial adenopathy, that these, as well as pulmonary tuberculosis in the child and adult, must be considered as resulting from a tuberculous infection of intestinal origin. After a complete consideration of the literature the following conclusions were offered: (1) That it was impossible to gain any knowledge as to the port of entry either from the location or the degree of development of the tuberculous lesions. (2) That fetal infection was proven but not common. (3) That infection through the mouth, tonsils, and pharynx was of frequent occurrence and might be produced by inhalation or ingestion. (4) That primary inhalation infection through the lungs did occur. (5) That infection through the intestinal tract was definitely proven. (6) That the bronchial glands and lungs might be infected through the latter channel as well as through the lungs. (7) That the relative significance of the various modes of infection was very difficult to determine, on the basis of their present knowledge, since it had been clearly shown that it mattered not from what point the tubercle bacillus was introduced it could eventually reach the bronchial glands and lungs without leaving any evidence of its mode of entrance. It was possible, however, on account of the greater exposure of those portions of the body, that infection through the upper respiratory and alimentary tracts was the most common, and next to this, for similar reasons, through the lower respiratory and intestinal tracts. He said he was prepared to believe that infection by the in-

testinal tract was more common in infants and children than infection through the lungs.

The Management and Treatment of Tuberculosis in Infants and Children.—Dr. John Lovett Morse of Boston presented this paper. He said that the general principles of the management and treatment of tuberculosis in early life were the same as in later life, but they had to be somewhat modified in their application because of the manner in which tuberculosis manifested itself in early life and because of the different ways in which children bore exposure and reacted to climatic conditions. The chief characteristics of tuberculosis in infancy were its malignancy and its tendency to dissemination. The restriction of tuberculosis to a single organ and the involvement of the lungs, as it occurred in childhood and in adult life, were very unusual. The fatality at this age was so great that little could be hoped from any form of treatment. In young children the tendency to localization was greater. The bones and serous membranes were much more frequently involved than the viscera, and there was a decided predilection for the lymphatic system. In older children the pulmonary lesions were more common, increasing directly with the age, but they were comparatively rare before puberty. The course of pulmonary tuberculosis at this age was more rapidly progressive than later. At puberty the lesions, course, and treatment were essentially the same as in adults. For practical purposes tuberculosis in children he divided into two classes, surgical, including scrofulosis and lymphatism, and visceral. Children suffering from surgical tuberculosis did better at the seashore than inland, especially if the climate was temperate. Experience at the Convalescent Home of the Children's Hospital in Boston, however, showed that they might do well inland and in a cold climate, but a stay of at least one year was necessary. Children of the erethitic type usually did better inland in comparatively mild climates. Children with pulmonary tuberculosis were less able to bear extreme cold than were those with surgical tuberculosis, and withstood hardening and exposure very poorly. The dietetic treatment of tuberculosis in early life was essentially the same as in adult life. The drug treatment was purely tonic and symptomatic. The susceptibility to opium in any form at this age should be remembered. He knew nothing from his own experience of the use of tuberculin in children. The children of tuberculous parents should be sent away if possible. Those suffering from latent tuberculosis, or if predisposed to it, should be given proper climatic treatment or sent to sanatoria. The great problem of the management of tuberculosis in childhood was to prevent its spread. All children in families in which there was open tuberculosis should be removed and sent to the country or seashore. Schools should be inspected at least once in six months and those scholars infected with the disease should be sent to sanatoria. Fresh air schools should be established. For those who could not be sent away, day camps should be established. Advanced cases should be treated by themselves in special hospitals.

Dr. David Bovaird, Jr., opened the discussion by considering the relation between bovine and human tuberculosis and calling attention to the two schools whose claims were so directly opposed to each other.

Dr. Henry Dwight Chapin called attention to the difficulties encountered in making an early diagnosis of tuberculosis in infants and children and cited an interesting case. While tuberculosis in cattle seemed to be increasing, it was a noteworthy fact that tuberculosis in man was decreasing.

Dr. Harlow Brooks said that the anatomical lesions were not infallible in pointing out the location of the tuberculosis invasion. He had found that tuberculous infection in the orang-outang and chimpanzee could be prevented by attention to the respiratory tract; preventing the possibility of infection by the respiratory tract wiped out an epidemic in his experience.

Dr. William P. Northrup said that one of the most iniquitous things in cities to-day was the overheating of the houses, as well as the excessive variation of the heat. If one could not have continuous heat, it was better that the atmosphere should be cold. A dry skin kept one from catching the so-called "cold." One of the best ways to prevent tuberculosis was to cool the houses. He was surprised at Dr. McCrea's statement that tuberculoma in the brain was about one-fourth as frequent as meningeal involvement. In his experience tuberculosis occurred but very little in the brain itself, and it was surprising how limited it was to the meninges. The Calmette reaction was a most remarkable phenomenon, and was of great aid in diagnosis.

Dr. Roland G. Freeman said that there were a great many cases which at autopsy apparently were of inspiration tuberculosis, but which were really cases of intestinal tuberculosis, with little or no trace of the site of inoculation left. It should be remembered that milk from tuberculous cows often contained no tubercle bacilli.

Dr. A. F. Hess spoke of the relative practical importance of bovine and human tuberculosis, especially as concerned infants and children. By means of the morphology and of cultural and biological tests, the human and bovine types might be distinguished. In speaking of the deductions that might be drawn from the work already done, he said that it had been shown that primary tuberculosis of the lung was almost invariably caused by a bacillus of the human type. Laboratory methods might enable us to make a clinical entity of bovine or human tuberculosis, so that we might be able to diagnose it without the time-consuming methods of isolating cultures.

Dr. A. Jacobi disagreed with what Dr. Morse had said regarding the giving of opium in these cases, for opium was not a rank poison for little babies and children when they had tuberculosis. Otherwise he believed Dr. Morse's paper to be one of great value, showing the results of a wide experience. Dr. Jacobi advocated bringing milk to the boiling point instead of attempting to pasteurize it; one then would be sure to obtain the proper temperature.

Election of Officers.—After the adjournment of the regular meeting, the following officers of the Section on Pediatrics were elected: *Chairman*, Dr. Godfrey R. Pisek; *Secretary*, Dr. Eli Long.

Stated Meeting, Held January 16, 1908.

The President, Dr. John A. Wyeth, in the Chair.

Clinical Notes on Laryngeal Phthisis.—Dr. Beverley Robinson read this paper, presenting his personal observations and experience on tuberculosis as it appeared in the larynx, together with certain facts pertaining to its management and treatment. For many years he had had an extensive opportunity of seeing and treating this condition. In a fair proportion of the cases pulmonary tuberculosis had laryngeal complications. Laryngeal phthisis was more frequent among men than women because the former were exposed more by their different occupations in which the larynx was exposed to irritation. A laryngeal examination might frequently fix the diagnosis which was obscured prior to it. There were few, and sometimes no, laryngeal symptoms. Sometimes the patients presented huskiness, hoarseness of voice, intermittent or remittent, which was often treated as a slight cold; the appearance of the larynx under the laryngoscope would differentiate it as laryngeal tuberculosis. In those cases with a marked hoarseness, with pain, with dysphagia, etc., such an examination should always be made. In young adults with a cold or cough, which persisted despite rational treatment, and where the causation seemed obscure, one should invariably insist upon a laryngeal examination. By judicious management one might prevent the disease from going on. He admitted that the general treatment which was the wisest

or best in pulmonary tuberculosis was judicious often in laryngeal complications. In the treatment two things he insisted upon, rest for the larynx and inhalations. In some sanatoria for tuberculosis, where the larynx was affected, complete silence was insisted upon; spoken words were not allowed, but writing pads were furnished all such patients. Such a method gave the patients a far better chance for cure. In no disease was rest so useful as in disease of the larynx. In a few instances tracheotomy had been performed for laryngeal tuberculosis with stenosis, and this apparently modified the disease favorably by giving rest to the larynx, which this measure afforded. Dr. Robinson said that formerly he made use of atomized solutions, iron with glycerin, etc. When there was edema of the laryngeal folds or of the glottis, or posterior portion of the larynx, he often used alkaline carbolic spray as the best cleansing application before he used zinc, iron, or other agents. These were used in moderate strengths. Whenever there was ulceration attempts were made to reach the ulcer directly with stronger pigments by means of a probe on which chromic acid had been fused. When there were excrescences present he used the tube or other form of forceps. In no instance had he made use of intralaryngeal injections, a method of treatment that never appealed to him. To punch an infiltrated or hardened tissue over the cartilage he did not believe was indicated or desirable. If the ulcer was localized or single it might be moderately curetted with advantage; while he had not attempted this, he saw no objection to it. After these excrescences were in part or wholly removed by the forceps, then applications might be made. Formerly, when the patients had laryngeal pain, ulceration, infiltration, etc., he applied iodoform or morphine or both combined; this lessened the patient's suffering and made deglutition easier. Again the position with the head over the bed and sucking fluids through a rubber tube afforded some relief. To-day these patients were relieved by the use of orthoform, a drug which had the advantage of being innocuous. Among applications to ulcers of the larynx lactic acid in 10 per cent. to 80 per cent. solutions, or even pure, was used this helped to complete the healing of the ulcer. If lactic acid was to be applied in strong solution, or pure, it should be done with great care to avoid undue pain or distress. Its curative effects were much increased by complete rest of the larnyx. In rare cases where the epiglottis was the seat of ulceration, with dysphagia, it might be found desirable to remove it with the knife or snare. The most important local measure to be employed by the sufferer from laryngeal tuberculosis at any stage of the disease, was the persistent, long-continued use of the perforated zinc inhaler (see Fig. 1, page 297), using creosote and alcohol, combined, or not, with spirit of chloroform. This was of great value. In 1885 Dr. Robinson read a paper on antiseptic inhalations; at this time he drew attention to their value in bronchial and laryngeal diseases. The inhalations modified the sputum, diminished its quantity, lessened the cough, promoted sleep, etc. He said he knew of no other method or surgical measure which afforded the same amount of relief of symptoms or promoted a cure in suitable cases as the use of this perforated zinc inhaler with the fluids mentioned. According to the researches of Horn, 97 per cent. of the cases of pulmonary tuberculosis had symptoms referable to the larynx during the course of the disease. The use of tuberculin might establish beyond a doubt the existence of tuberculosis. Calmette's reaction was a great advantage. Tubercle bacilli in the feces might aid in the diagnosis. The *x*-ray was also of value in certain cases.

Dr. A. Jacobi said that his remarks referred to the lymph connection of the larynx with the rest of the body. The lymphatics of the larynx had been studied mainly by Sappey in his famous atlas, by P. Poirier and B. Cunéo in the second volume in "Poirier et A. Charpy, Traité d'Anatomie Humaine," 1902, and by Aug. Most, *Zeitsch f. d. Chir.* 1900 and his "Topographie des Lymphgefass-Apparates des Kopfes und des Halses," 1906. The lymphatics of the larynx were most copious where the mucous membrane was the most thick and succulent, viz., in the region above the vocal cords; very much less below the vocal cords where the mucous membrane was very thin. Here the lymphatics were scarce and so narrow that their infection was attended with great difficulty and mostly failed. The anastomoses of this portion of the laryngeal lymphatics with the digestive and respiratory organs, viz., tongue, pharynx, and trachea, were defective. The upper part of the larynx was connected with the lymphatics located along the jugular vein. The subglottic part had no or few such connections. Indeed, the small glands found on the level of the thyrohyoid membrane, received no lymph vessels from the larynx at all, but from the pharynx and the epiglottis and arytenoid part of the larynx. The lymphatics of the trachea resembled very much those of the lower half of the larynx. There were four lymph outsets from the larynx, two lateral ones from the upper, one anterior and one posterior from the lower part of the larynx. These latter were very thin and few in number. All of these lymph connections were of vast importance to the surgeon dealing with carcinoma of the larynx. As long as the tumor was lateral it affected the glands of the same side. Thus the location of a metastatic glandular tumor serves as a rule in making the diagnosis of the tumor. Bilateral metastatic tumors indicated the bilateral seat of the cancer. Tuberculosis of the larynx did not affect the neighboring glands to the same extent. Even the deep cervical glands were more frequently infected from the pharnyx than from the larynx. Peritracheal glands were rarely tuberculous. The prelaryngeal glands swelled in a few cases only. When they were found, however, even when of small size, bacilli could be demonstrated (Most, p. 125). But they were not often found. This agreed perfectly with other clinical observations. We had known this third of a century that, for instance, in cases of diphtheritic croup, when the membrane was confined to the larynx exclusively, necessitating tracheotomy or intubation, the system did not participate in the process at all. There were no constitutional disturbances. That was shown by the absence of fever and the absence of swelling of the lymph bodies of the neighborhood. This observation was even more positive than the relations to diphtheria of the tonsils, which, so long as they were the exclusive seat of a diphtheritic exudate, gave rise to no, or very little, glandular swelling. These anatomical remarks, he said, covered all cases of laryngeal tuberculosis, both secondary and primary. The latter, though rare, might occur at all periods of life, even in the nursling. The few cases occurring in the latter were complicated with extensive tuberculosis of the bronchial glands. The explanation of this complication was furnished by the changes which took place in the anatomy of the several periods of life. In all mucous membranes the lymph vessels decrease in size and numbers with advancing years; in the intestine, in the pharynx, principally in the tonsils, and mainly in the larynx. The prevailing diphtheria of this half century and universal observation proved that anatomists had learned that the injection of lymph vessels in the newly born was easy, began to be difficult in children a few years old, and was very difficult or impossible in many localities in the adult body. That was why the bronchial glands were easily affected by the primary tuberculosis of the larynx in the newly born, and why with increasing years the same local disease might not, or but little, spread to the lymph circulation of the body at large, and might remain localized. Indeed, the relative absence of general tuberculosis in laryngeal phthisis was often observed. Dr. Jacobi said he had had very little experience with the local treatment of the tuberculous larynx, but he saw a good deal of pharyngeal tuberculosis in its complication with tuberculosis of the larynx and lungs. We were well acquainted with the

fierce suffering of dysphagia in such cases. Gargles did no good. They never reached the posterior wall of the pharynx, for there were very few who would ever learn how to reach it and expel the fluid through the nares. He liked to spray the throat, either directly or through the nares, once or twice a week with a one or two per cent. of nitrate of silver solution. The excessive pain caused by swallowing might be relieved or removed by the use of small doses of morphine a few minutes before each meal. A hypodermic tablet of one-eighth of a grain, more or less, was placed on the tongue and sucked down without water. Its absorption was local and required but a few minutes. This was very little more than that of the same amount of morphine used subcutaneously for other purposes. Four or five drops of Magendie's solution, not diluted, applied in the same way, had the same effect. Finally, he said, he had always protested against leaving any tuberculous patients—and mainly those with pulmonary tuberculosis—alone with fresh air, good food, sanitarium treatment, and all that. For seventeen years he had treated tuberculosis with guaiacol, or, better still, if the patient was not too poor to pay for it, a guaiacol salt, preferably the carbonate. Good creosote contained only 60 per cent. of guaiacol. He knew it worked well. If he had any voice in the matter, no sanitarium patient would be treated without a preparation of guaiacol year in and year out. He was certain that he had given it in these seventeen years to five thousand patients. He said he would continue doing the same in the next seventeen years unless he found something better. We were frequently, indeed, in a position to utilize the evidence of clinical experience and to learn the reason and the theory afterwards. It might be that the guaiacol acted as an intestinal antifermentative only; it might be, as he believed, it had a peculiar antidotic action on the circulating toxin of the bacillus.

Dr. Walter F. Chappell wished to contribute some clinical notes on laryngeal phthisis, and desired to dwell briefly on primary laryngeal tuberculosis, avenues by which the tubercle bacillus entered the mucosae of the larynx, diagnosis and treatment. In regard to primary laryngeal phthisis he said that at every discussion on tuberculous infection of the upper air tract, the primary method of infection should be strongly presented as the acceptance of a possible primary infection cleared up many cases which were doubtful in former times, and added greatly to a favorable prognosis. His experience had prepared him to believe that primary disease in the upper air tract might be viewed from the aspects of its pathology, diagnosis, prognosis, and treatment, without any infection being present in the lungs. Not infrequently the tubercle bacillus gained an entrance into the mucous membrane of the larynx without producing any serious disturbance. Its subsequent history depended upon the personal equation of the mucous membrane of the individual. Mild infections were often unrecognized and entirely recovered. Severe primary infections were rather uncommon and their prognosis unfavorable. There was considerable mystery in regard to the avenues by which tuberculous infection entered the upper air tract. The common sense theory of direct infection through a damaged mucous membrane was in his belief the reasonable view, and was amply supported by clinical facts. It applied alike to primary and secondary forms of tuberculosis. This form of superficial infection produced more or less superficial disturbances of the mucous membrane and might be arrested in a short time or continue through the various stages of tuberculous laryngitis. Three stages were recognizable, the premonitory stage, the advanced infiltration stage, and the ulcerative stage. In regard to a recognition of the premonitory stage, he said that he believed that more or less definite symptoms preceded the deposit of tubercle in the larynx. Many catarrhal inflammations had a close relation with this infection, but it was often difficult to determine whether they were cause or effect. He had frequently seen severe laryngorrhea in a tuberculous patient continue for months before a definite diagnosis could be made. Recurring superficial, local hyperemia were the usual characteristic signs of early laryngeal tuberculosis. The interarytenoid space, ventricular bands, and epiglottis were the usual locations for early circumscribed infections; persistent redness and thickening of these locations in a tuberculous patient should cause anxiety. The ulcerations following a surface infection were superficial and usually quite extensive in area. Sometimes the initial appearance was a gradual thickening of the deeper tissues of the larynx, progressing slowly one or two years until most of the interior of the larynx was filled with thickened tissue and local tumefactions. When ulceration occurred it was small, deep, and increased very slowly and not infrequently healed with special local treatment. These cases were, in his experience, always secondary to pulmonary tuberculosis, and he thought the infection took place through the pulmonary vessels and entered the larynx through its vascular supply. These patients usually gave a history of more or less pulmonary hemorrhage with cavity. There was little that was new in diagnosis, but some irregular cases taxed all one's skill and experience, as, for instance, syphilis affecting the cartilage of the larynx, producing a thickening and bulging of the mucous membrane of the larynx, resembling tuberculous tumefactions. Mixed infections of syphilis and tuberculosis were not infrequent and were difficult to make out. Constant pain in laryngeal ulcerations was a prominent point in favor of tuberculosis. The subcutaneous tuberculous test had been of value in doubtful cases. He had employed Calmette's test with positive results in one case and hoped that it might be brought into more general use. He said that no uniform treatment was applicable to all cases. Laryngeal rest was most important in all cases and could be obtained by absolute cessation of the use of the voice and also by all the milder forms of infection and to ulcerations in all stages. To be effective it should be continued for three months or longer. Treatment might be classified as medicinal, surgical, and climatic. In the early stages soothing sprays and warm inhalations such as oleum pini pumilionis, creosote, menthol in milk of magnesia, were of value. When the tuberculous infiltrations were large, submucous injections of lactic acid and creosote might be used, but only in the quiescent stage when there was no fever. When the disease had progressed to the ulcerative stage all applications of an irritative character were contraindicated. When the temperature was normal and the laryngeal infection in a quiescent stage, applications of 25 per cent. lactic acid might be used or the creosote solution. The general aching of the laryngeal region might be relieved by the external application of menthol, camphor, and chloral hydrate. The icebag was also beneficial. Tracheotomy should be done in severe cases, when there was great infiltration of the mucous membrane threatening life. In four cases the operation had proved satisfactory in his practice, the urgent dyspnea being immediately relieved, and later the great thickening receding. In all cases a temporary arrest of the disease was effected. Tracheotomy in ulcerative conditions was harmful and he could not speak too strongly against it, as well as against the removal of tuberculous thickenings and ulcerations by means of cutting forceps and sharp curettes. When the curette was used it should be dull and employed gently in scraping a tuberculous ulcer. When more heroic measures were employed new avenues of infection were opened and the disease spread rapidly. In regard to climatic treatment he said he would rather take his chance in a good climate without treatment than in a poor one with the best of treatment. It was not easy to decide just what was the best climate. Residence near the sea or a large inland body of

water was not good for tuberculous throats. In the early stages a dry, cold climate was beneficial. If the disease process was active a moderate temperature was important. High winds and damp, foggy days were bad for all ulcerations. As a rule, tuberculous throats were better in a moderately warm, dry climate free from dust and winds. In his opinion the future of all arrested cases, either laryngeal or pulmonary, depended upon early diagnosis, and the patient's willingness and financial ability to keep himself under proper climatic and hygienic treatment.

Dr. Joseph W. Gleitsmann said that several years ago he had pointed out the importance of the consideration of the lymph glands in laryngeal cancer. In many cases of laryngeal tuberculosis the lymphatic glands were hard to the touch. Infection was not always as some claimed it to be, by inhalation; it arose simply through the lymphatic system. It had been shown, and in a clear manner, by some French observers, and others, that tubercle bacilli could enter an intact epithelium without leaving a trace. This also explained some infections occurring by the tubercle bacilli entering through the intact mucous membrane of the intestinal canal and causing tuberculosis elsewhere. He wished to testify and bear testimony to the good effect of guaiacol, especially in dispensary work. He was glad to have heard Dr. Robinson call attention to the perforated zinc inhaler. Dr. Gleitsmann said he had heard of it, but had never used it. Absolute silence did much good. Advanced cases must be treated differently from the acute cases. The early cases of laryngeal tuberculosis were not easily diagnosed. He said we had been taught that in laryngeal tuberculosis there was at first anemia of the vocal cords or laryngeal walls; this he could not confirm. The vocal cords were not anemic, but congested, and showed minute vessels on the surface. There might be, however, a unilateral hyperemia in tuberculosis here. Horn had emphasized the importance of recognizing this. A point that was new to him was the importance of the infiltration of the interarytenoid spaces he was speaking of the puffiness or fullness of the posterior walls of the interarytenoid spaces. Dr. Gleitsmann then referred to laryngeal tuberculosis occurring in pregnant women, and said that, in such cases, some observers advocated artificial abortion. Some observers had seen cases far advanced in laryngeal tuberculosis give delivery to healthy children. With regard to the treatment, he said that lactic acid should be applied only after the ulcers had been first cleaned. In 1885 or 1886 he recommended the application of lactic acid simply for ulcerations of the larynx, and not for infiltration. If the acid were applied properly and not smeared around promiscuously, it acted upon the ulceration proper and left an intact mucous membrane. It had no effect at all in reducing the infiltration.

Some Notes on the Etiology, Prophylaxis, and Therapeutics of Laryngeal Tuberculosis.—Dr. S. A. Knopf and A. J. Huey read this paper (see page 297).

Dr. Francis J. Quinlan called attention to the objective and subjective picture in laryngeal tuberculosis. One was dealing here with a condition which had symptoms, such as cough, dyspnea, huskiness, dysphagia, etc., and these symptoms, more or less verified by the objective signs as shown by the laryngoscope, made it almost impossible to mistake the nature of the trouble. But the subjective must be reinforced by the objective signs. The diagnosis could be made by attention to the temperature, the pulse and the respirations, and above all by an examination of the sputa. In many instances the remedial agents did not reach the parts, because the parts were covered with mucus, layers of mucus, and pus, and myriads of bacilli. Unless the parts were first cleansed thoroughly the things advocated would be useless. He had used with satisfaction the vapors spoken of by Dr. Jacobi. The patients, however, should be built up. Cough was an explosion, a reflex act, and this could not be controlled by ordinary measures. The parts should be put at rest, and cocaine was the only thing of benefit in such cases. Formaline, lactic acid, and other agents were beneficial. The dyspnea could be controlled in many cases by the use of nitrate of silver. When the patient's life was in danger, tracheotomy should be thought of.

Dr. Emil Mayer said that in the main he agreed with what Dr. Chappell had said. Doing a tracheotomy had shown him the advantage which followed such an operative procedure in prolonging life and even enabling a cure to result. He took issue with one statement made in which Dr. Chappell said that he himself preferred climate treatment rather than the best laryngeal treatment; this statement he took issue to. It was best to give both. The patient should be sent to a place where he could be kept under the care of a laryngologist, and where he could get advantage of the air as well. For some time they had an arrangement at the Mount Sinai Hospital whereby when a patient came directly to their department with all the evidences of tuberculosis of the larynx he was referred to the department of internal medicine with the request for a report. Invariably a report was received from that department, and the work was checked off. They made the diagnosis, which was confirmed by the department of internal medicine. With regard to the treatment, many of the things suggested were not of great value. Some cases would do well under intratracheal applications. He advocated the use of a glass tube with a rubber bulb so arranged that the patient could apply the orthoform emulsion directly to his own larynx. The emulsion used was that suggested by Dr. Freudenthal, a combination of orthoform with morphine and cocaine.

Dr. Thomas J. Harris said that, in his own experience, he had arrived largely to the same conclusions already drawn by Dr. Robinson. He did not believe in meddlesome interference in laryngeal tuberculosis. With regard to the use of extensive surgical procedures, they did not seem to do good in the patients that came to him. He believed in the great value of rest, and called attention to the case of a distinguished specialist who went without speaking for one year, and to-day was a cured man. With regard to the local treatment, there was in his opinion one thing better than anything else where active local treatment was required, and that was galvanocautery. He had never seen any decided or severe reaction follow its use. This offered a means of getting at the seat of the disease and without reaction.

Dr. Robinson closed the discussion. He wished it to be understood that he meant all that he had said. He was absolutely sure and convinced that there was no one single thing that would do half the good as the proper, consistent use of what he had told them about. Once again, he could not emphasize too strongly the value of the perforated zinc inhaler with the inhaling mixture mentioned. He believed the inhaler should be used not only in every dispensary, hospital, sanatorium of the country, but also very widely in private practice whenever and wherever indicated.

Bed Sores.—When a patient is to be in bed for a long time, as in fracture of the thigh, great care must be exercised that bed-sores do not form. In the first place linen draw-sheets must be made, sufficiently large that they may be firmly fastened to the sides of the bed so as to prevent creases or wrinkles forming under the body—these and dribbling urine being the most frequent causes. Whenever the sheets become soiled by urine, feces or discharge from a wound, they must be changed. As soon as the slightest redness of skin is observed the affected surface must be rubbed with alcohol (65 per cent.) and dried and then carefully anointed with glycerin; twice daily at least. Or equal parts of tincture of catechu and liquor plumbi may be substituted for the glycerin if that causes much smarting, as it sometimes does.—*American Journal of Clinical Medicine.*

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at St. Louis, Mo., December 30 and 31, 1907.

THE PRESIDENT, DR. CHAS. W. OVIATT OF OSHKOSH, WIS., IN THE CHAIR.

(*Concluded from page 289.*)

Lymphatic and Portal Infections Following Appendicitis.—Dr. ROLAND HILL of St. Louis, Mo., reported an interesting and unique case illustrating these infections, and said that in the present stage of surgical knowledge we were almost absolutely helpless in the presence of some of the severe forms of infection when the infecting organism had once passed into the general circulation. It went without saying that early removal of the appendix should be the keynote in all cases, together with an attack, wherever possible, upon any focus that might form. Considering what had been accomplished along the lines of serum therapy, the remarkable effects of antitetanic serum as a prophylactic of tetanus, and the miraculous results of diphtheria antitoxin, it did not seem too much to hope and expect that experiment medicine would soon offer specific agents which would nullify the effects of the various pathogenic organisms when once they had been introduced into the blood.

Extrauterine and Intrauterine Pregnancy of Five Months, with Operation and Death.—Dr. D. C. BROCKMAN of Ottumwa, Iowa, reported the case of a woman, five months pregnant, with extra and intrauterine pregnancy. An attempt was made to remove the ectopic sac by abdominal section, but the parts were so vascular that he was obliged to desist. Furthermore, the patient was so debilitated from vomiting that he did nothing further. But in ten days he opened the sac from below, removed the fetus and packed the cavity with gauze, intending to remove the placenta later. Uterine hemorrhage and pains occurred on the third day, and the woman died two days later from extra- and intrauterine hemorrhage. He asked, could a better method be suggested?

Dr. D. W. BASHAM of Wichita, Kan., reported a case of hernia of the appendix, which was complicated with appendicitis, and reviewed the literature on the subject.

Sexual Perversion as an Accompaniment of Prostatic Hypertrophy.—Dr. J. F. PERCY of Galesburg, Ill., believed that the old prostatic, who showed aberrant sexual activity, was in a large proportion of cases suffering from a psychosis rather than senile dementia, to which the symptoms were usually attributed. Under the influence of the irritation from his enlarged prostate, he might commit all forms of sexual crime, and after removal of his prostate his functional sexual aberration disappeared, and he remained cured. This phase of the diseased prostate opened up the possibility of a more rational study of the pelvic environment of the prostate gland in the sexual perverts among men, old and young. Many old prostatics were in insane asylums, many of them were in the government and state soldiers' homes, as well as in the various county almshouses. The strain of sexual excesses from early life until old age, the intimate connection maintained between the prostate gland and the sympathetic and the cerebrospinal nerves, the unknown secretory functions of the prostate gland along physiological lines—these all made prominent the fact that with the hypertrophied prostate could be had a class of symptoms referable to the sexual system, where the mental life of the sufferer carried him close to the border where insanity had its dominion, and which could be corrected by the aid of surgery.

Intestinal Obstruction.—Dr. B. MERRILL RICKETTS of Cincinnati, Ohio, contributed a paper on this subject, in which he defined obstruction as the stoppage or blocking of a canal or opening in the body, due to any of the numerous causes. The symptoms such as vomiting, pain, distention (symmetrical or asymmetrical), sweating, collapse, rigid parietes, and toxemia, one or all might be present in any form of obstruction in the large as well as in the small bowel. These being facts, why should exploration be delayed, when simple incision through the abdominal wall was done without mortality? Should exploration and direct digital and ocular examination of the abdominal viscera be delayed in intestinal obstruction, because experiments, reports, symposia, and discussions had failed to satisfactorily explain its etiology, symptoms, and treatment? Intestinal obstruction probably had a higher immediate mortality with or without surgical intervention than any of the surgico-pathological diseases. The non-mechanical type without operation had a supposed mortality of 90 per cent. when not complicated with general peritonitis, and from 60 to 84 per cent. with operation. This mortality in post-operative obstruction exceeded that of preoperative obstruction of the same degree, whether of the mechanical, non-mechanical, or septic type. This increased mortality was due to the added surgical trauma, and especially the anesthetic. In the mechanical type the mortality was given as 100 per cent. without operation, and from 50 to 80 per cent. with operation. This difference in per cent. was probably due to the advantages of palpation and the Roentgen ray in detecting neoplasms and foreign bodies, which were its most common cause, hence earlier surgical measures might be resorted to. In the septo-peritonitic type without operation the mortality was generally given as 100 per cent., while with operation it was somewhat less. There were certain forms of obstruction with or without infection that had been considered invariably fatal. If this was so, there was nothing to be lost in opening the abdomen. If, after opening the abdomen, an imperfect mechanism within could be made perfect without destruction of the nerve or blood supply, in the absence of infection, surely many more cases would recover; even with many forms of infection this was probably so. But if the patient became exhausted from vomiting, pain, infection, or want of nourishment, with or without infection of any kind, the mortality would be proportionately high. Pain, distention, and vomiting were always alarming, and the majority of patients went on to death regardless of any effort to relieve them. Intoxication had not yet been proven to be the cause of death in any given case of obstruction. If cases of obstruction indicated by one or more symptoms were opened at the onset, under ordinary precautions, the mortality would be less than if they were operated upon late in the attack. The element of delay in surgery is more serious than the element of aggressiveness. In no other surgical condition was this statement more fully verified. The most skilled operators had many times opened the abdomen for a condition made certain by one or more symptoms, and found one entirely different. If this was sanctioned in other lesions of less importance within the abdominal cavity, why could not exploration for obstruction based upon one or more symptoms be undertaken? This would determine the character and degree, if obstruction was present. If not present, no special harm would ensue. If the character or degree or both were believed to be fatal, the remedy should be applied regardless of its character, because that verdict was only an opinion, not an established fact.

Dr. A. A. KERR of Salt Lake City contributed a paper in which he discussed obstructions of the common bile duct and reported a case in which he performed cholecystostomy, partial gastrectomy with posterior gastrointestinal anastomosis, cholecystenterostomy, and enteroanastomosis.

The following papers were also read: "Hydrocephalus, Its Surgical Management," by Dr. Wm. Jepson of Sioux City, Iowa; "Sarcoma of the Liver," by Dr. Van Buren

Knott of Sioux City, Iowa; "The Diagnosis and Treatment of Extrauterine Pregnancy, with Report of a Case," by Dr. Geo. C. Barton, of Minneapolis, Minn.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. W. W. Grant of Denver, Colo.; *First Vice-President*, Dr. Willard Bartlett of St. Louis, Mo.; *Second Vice-President*, Dr. Harry A. Sifton of Milwaukee, Wis.; *Secretary-Treasurer*, Dr. Arthur T. Mann of Minneapolis, Minn.; *Executive Council*, Drs. C. H. Mayo of Rochester, Minn., and J. F. Percy of Galesburg, Ill. Minneapolis, Minn., was selected as the place for holding the next annual meeting; time, December 29 and 30, 1908.

New Instruments.

A NEW STETHOSCOPE.

By DUNLAP P. PENHALLOW, M.D.,

BOSTON, MASS.

SURGICAL HOUSE OFFICER, BOSTON CITY HOSPITAL.

Some time ago I became interested in stethoscopes and, after considerable experimenting, devised one which was small, light, simple of construction, and at the same time one which gave a clearer and a relatively louder sound than any of those with which I am familiar.

The instrument consists essentially of a solid metal body containing a relatively deep cone (Fig. 1), from the apex of which leads a metal tube to

Fig. 1.

which the rubber tubing of the binaurals can be attached. The size of the instrument is such that for localizing lesions, such as cardiac murmurs, it is invaluable. The sounds are brought out clearly and distinctly, without being confused with sounds from surrounding organs, as is the case when a larger bell is used. In comparing this instrument with others I have found that murmurs which were inaudible with stethoscopes of a larger size could be heard distinctly with this small bell. The sounds are of a much clearer tone than those produced by others, and, in addition, they are of a relatively greater volume. The size is such that the instrument may easily be used in the supraclavicular or in the intercostal spaces.

The construction is shown in the accompanying diagram (Fig. 2) in cross section, and consists of the body (*a*) in which is the cone-shaped air-chamber (*b*), which is relatively very deep. From the apex of this air-chamber leads the tube (*i*) to which the binaurals may be attached. The body of the bell is flat, as is shown in the diagram, with rounded edges. Close to the lower edge of the bell is a groove (*f*) into which is fitted a spring ring (*e*), which is used to hold the diaphragm in place. The diaphragm (*d*) consists of some easily vibrated material, such as sheepskin, which is applied while wet and is stretched into place by means of the ring, which then holds it firmly. When the skin dries it becomes tense, thus forming a very sensitive diaphragm. After the diaphragm is in place it may be covered with paraffin, which renders it impervious to moisture, and thus prevent the absorption of moisture from the body of a patient.

Diseases of the Nose and Throat. By D. Braden Kyle, A.M., M.D. 8vo, 797 pages, illustrated, cloth. W. B. Saunders Co., Philadelphia.

Minor Surgery. By Edward Milton Foote, A.M., M.D. Large 8vo, illustrated, cloth. D. Appleton & Company, New York.

Comparative Electro-Physiology. By J. C. Bose, M.A., D.Sc. 8vo, 760 pages, illustrated, cloth. Longmans, Green & Co., New York.

Variations of the Bones of the Hands and Feet. By Thomas Dwight, M.D., LL.D. Royal 8vo, illustrated, cloth. J. B. Lippincott Company, Philadelphia.

Light and X-Ray Treatment of the Skin. By Malcolm Morris, F.R.C.S. (Ed.) and S. Ernest Dore, M.D. (Cantab). 12mo, 172 pages, muslin, illustrated, $1.50 net. W. T. Keener & Co., Chicago.

Medical Items.

Modifications of the Bacterial Flora of the Intestine Under the Use of Buttermilk.—Eduardo Gilberti and Giovanni Centela have examined the feces of infants suffering from various gastrointestinal affections and taken buttermilk as a diet to ascertain its effect on the bacteria contained in the intestine. The authors find that the pathogenic bacteria are hindered in their growth, while those microorganisms that prevent putrefaction and antagonize the pathogenic bacteria are aided in their growth. Buttermilk is an efficient food and one of easy assimilation, and acts as a therapeutic agent as well. The action of buttermilk is also due to the special chemical condition of the food which produces important modifications in the contents of the digestive tube, it having a marked antifermentative action due to the scarcity of fats. The fats aid in the production of putrefaction in the intestine. Buttermilk develops the physiological saprophytes. The feces become modified in from thirty-six to forty-eight hours after the use of buttermilk begins, and soon become normal.—*La Pediatria.*

Night Blindness.—At a recent meeting of the Ophthalmological Society of the United Kingdom, Nettleship gave some interesting facts concerning a genealogy of ten generations of congenital, stationary night blindness. This disease, often hereditary, was, he said, less known than retinitis pigmentosa and its so-called unpigmented variety, and, unlike them, did not progress. A great part of the present case was published by Cunier nearly seventy years ago, and had been mentioned by many writers. But the nature of the disease was unknown until a year ago, when, at Mr. Nettleship's request, Professor Truc of Montpelier examined several living night-blind descendants, established the diagnosis, and instituted a fresh inquiry, resulting in an extension of Cunier's tables from upwards of 600 persons in seven generations, to nearly 1,800 in ten generations. Only certain branches of this large tree, containing about 260 persons, bore the disease, and of this number just one-half (129), contained in 60 childships, were affected. In half the affected childships (29) the proportion of disease to healthy agreed with the Mendelian theory; others showed a near approach to agreement, and others again, would conform if the dominance were supposed to have been reversed. About a quarter of the cases seemed inconsistent with Mendelism, but incompleteness of record doubtless accounted for some of these. The disease always passed from parent to child without a break, was rather commoner in females than males, did not lead to blindness, and was not accompanied by any other defects or peculiarities. It was not due to consanguinity; there were two first-cousin and seven second-cousin marriages, and only one of these nine produced night-blind children.—*The Lancet.*

Lactation and Typhoid Fever.—M. Péhu discusses the advisability of continuing lactation during the course of typhoid fever, both from the standpoint of the mother and the child. He draws his conclusions from the observation of five cases seen in the hospital at Lyons. It has been established that lactation is not desirable in such acute infectious diseases as variola, scarlatina, and diphtheria, but typhoid fever has not been always classed with them. He finds that the mammary gland acts as an efficient filter against the typhoid bacilli and that the disease is rarely transmitted to the child. There is no especial gravity in typhoid arising during lactation. In the author's cases lactation did not seem to harm the mothers, and convalescence was established at the usual time, and was not especially slow. The use of cold baths did not seem to have any effect on the function of the mammary glands. The secretion of milk was diminished, but continued for a considerable period of time. The disease was not transmitted to any of the children, although one presented the seroreaction of Widal in a slight degree. The mother's milk in this case also gave a reaction of agglutination. The normal mammary gland does not allow of the passage of germs which circulate in the blood. The microbes must first alter the epithelium of the glands.—*Annales de Médecine et Chirurgie.*

Population in Germany.—The recently published statistics for the year 1906 show very encouraging conditions in Germany. The number of deaths was 1,174,464 as opposed to 1,255,614 in 1905, the smallest absolute mortality since the formation of the German Empire, except for the year 1896. The rate per 1,000 was 19.2, the smallest on record. The number of births was 2,084,739, also a gain over the previous year. The improvement is attributed largely to the advances in the control of epidemics and in checking infantile diseases.

Tobacco in England.—According to a recent estimate, $75,000,000 are spent annually for cigarettes by smokers in the United Kingdom, $45,000,000 for pipe tobacco, and $5,000,000 for cigars. It is calculated that 80 per cent. of the men and 20 per cent. of the women in the country use tobacco in some form. The average consumption of cigarettes daily is eight per man, while pipe smokers consume at least six pipefuls a day.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending February 14, 1908:

CHRONIC SIGMOIDITIS.

BY HEINRICH STERN, M.D.,

NEW YORK.

THE sigmoid flexure is the seat of some enduring inflammatory processes to which has been given the collective name of chronic sigmoiditis. This affection has as yet not found recognition in the text-books on general medicine, and even in the special works on intestinal diseases it is dealt with in rather a cursory fashion. Boas, for instance, in his "Diagnostik und Therapie der Darmkrankheiten"[1] (one of the best treatises on the subject), devotes just twenty-two lines to chronic sigmoiditis apart from the space which is occupied by the history of two illustrative cases.

There is one paramount reason why chronic sigmoiditis is so rarely thought of by the average clinician, and this is the vagueness and incompleteness of its symptom-complex as it is generally understood. Says Boas (loc. cit.): "By chronic sigmoiditis I understand a clinical picture in which there is a permanent sensation of pain belonging exclusively to the region of the S. Romanum." To this meaningless definition he adds: "Conforming therewith, the pressure-pain is localized exclusively in that region." As remaining symptoms of the affection he mentions "well-marked diarrhea with more or less admixture of mucus, or, the opposite, obstipation." Chronic sigmoiditis, according to this conception, consists therefore of a permanent sensation of pain and of pressure pain confined to the sigmoid region, together with diarrhea and mucous discharge, or, together with obstipation.

I know of no intestinal affection of a catarrhal nature which is accompanied by a permanent sensation of pain. If this were a fact, the knife of the operator would be still oftener resorted to than it is at the present day. An apparently continuous pain on the basis of a chronic inflammatory process in the intestinal mucosa is in reality a succession of painful seizures of varying intensity with shorter or longer intermissions.

The pressure pain, of course, is a valuable symptom if one is sure of his ground. In the presence of coprostasis in the descending colon and the sigmoid flexure pressure pain may be evoked in every instance. The pain elicited by pressure upon retained feces naturally varies much in severity, it may not be more than a slight intensification of the localized uneasiness, but it may also amount to real suffering and distress. Nevertheless inflammatory processes, situated in the parts of the colon which are immovable, or almost so, namely in the ascending and descending portions, may be often localized by means of the pressure pain. On the other hand, a chronic inflammatory condition in the sigmoid flexure, a section of the colon endowed with great locomotion, can hardly ever be designated to a definite position by palpation alone. The painful sensation in the region of the sigmoid flexure is not always circumscribed and may be quite diffuse at times. This diffusion of pain may be due to the mobility of the flexure but also to the fecal column causing distention of this, the narrowest portion of the colon. Again, by pressure upon the adjacent organs, the more or less displaced sigmoid flexure often precludes the recognition of chronic sigmoiditis and gives rise to all kinds of wrong diagnosis. Nonrecognition of chronic sigmoiditis is especially apt to occur when obstipation is its concomitant. Thus, in the female, the generative organs are commonly thought to be at fault: neuralgia of the left ovary, for instance, is a rather frequent diagnosis; catarrh of the small intestines, enteralgia, intestinal rheumatism, and even appendicitis are occasionally diagnosed,* and on account of a concurring cystitis, the affection in the male remains once in a while entirely unrecognized.

The third, respectively the fourth conjoint diagnostic phenomenon of chronic sigmoiditis according to Boas, namely diarrhea with more or less mucous discharge, or, the opposite obstipation, are certainly not occurrences which are pathognomonic of chronic sigmoiditis. In chronic inflammatory conditions of other parts of the colon we have to deal with the identical eventualities. Quality and quantity of the mucus, and the manner and degree of its admixture with the feces are practically the same when it is derived from any part of the alimentary canal downward of the splenic flexure of the colon. Cell elements and other histological bodies occurring in this mucus will not disclose the latter's seat of origin as will the epithelia in the case of pus in the urine.

It is, of course, evident that on the hand of the symptom-complex critically reviewed in the foregoing, the physician hardly thinks of anything else but of chronic colitis of the descending segment of the large bowel. Chronic sigmoiditis, however, is of much more frequent occurrence than is commonly supposed, and its recognition, not only on account of instituting the proper treatment, but even more so for the reason of preventing wrong therapeutic measures, is of decided importance.

Definition.—I would describe chronic sigmoiditis as a chronic inflammatory state of the sigmoid flex-

*It must be recalled that the loose fold of peritoneum which holds the sigmoid flexure in its position is of quite discrepant dimensions in different individuals. Thus, in the newborn the sigmoid mesocolon may be elongated to such an extent that the sigmoid flexure may be situated on the right side in proximity to the cecum. Also, in some adults, the entire sigmoid flexure does not lie within the left iliac fossa. In such instances the diagnosis of chronic appendicitis instead of chronic sigmoiditis is not to be wondered at. I know of a pertaining case, a young woman in whom during an interval of the apparent perityphlitic attacks the healthy appendix was sacrificed to a wrong diagnosis.

ure, characterized by frequent exacerbations, lasting from several hours to several days, of the otherwise more or less subdued phenomena, viz., tenderness or pain in the lower left lateral and median anterior regions of the abdomen increasing upon pressure, moderate abdominal distention, with some resistance in the left iliac fossa, slight elevation of rectal temperature, obstipation, burning and aching sensation in buttocks and left thigh, various nervous phenomena, and, frequently, vesicular irritation in males, and spasmodic leucorrhea in females.

Symptoms in Detail.—Inflammation.—The recognition of the local inflammatory process by means of the sigmoidoscope is synonymous with the diagnosis of the affection. In every instance of long-continuing colitis an examination of the lower portion of the colon should be undertaken. The electrical sigmoidoscope, of which there are a number of modifications on the market, is very well suited for that purpose. I am employing now an instrument which I had made on the Strauss principle, and which permits a direct inspection of the entire lumen of the greater part of the pelvic colon. However, a long Kelly tube and the reflected light will also render good service. Only by sigmoidoscopy can we come to an appreciation of the real extent and intensity of the local inflammatory state. By the direct inspection we learn that an inflammatory process of the sigmoid flexure may be entirely confined to that part of the colon. In the majority of cases examined by me the descending portion of the sigmoid flexure was the seat of the inflammation. Of course, an inflammatory process of the sigmoid, especially in its lower part, may extend into the rectum, and, as a matter of fact, the inflammation involves the portion of the rectum nearest to the junction of the sigmoid, in a goodly proportion of pertaining instances. In other instances, the inflammation undoubtedly extends upwards and into the descending colon. Naturally, only such inflammatory processes are considered here, which take their origin in the sigmoid flexure, and not those cases of general colitis that, spreading downward, entangle the sigmoid flexure.

The pathological changes in chronic sigmoiditis are mostly confined to the mucosa. In about one out of four cases the cellular coat is involved. The muscular coat is not very frequently affected. We may find all gradations of the inflammatory process, from simple hyperemia to circumscribed and diffuse suppuration. The condition mostly encountered is exudative in character, with partial or more or less complete organization and marked induration. The inflammatory swelling is quite hard as a rule and seems to interfere with the free mobility of the affected area. Hypertrophy of the interstitial connective issue may be present to such an extent that the lumen of the affected segment of the sigmoid flexure may be considerably narrowed. A slight contraction at the site of the inflammatory process is almost always noticeable in cases of very long standing. As a result of ulcerative processes in the mucosa we may find a cicatricial stenosis. Cicatrization, ensuing on one side, may occasion kinks or twists of the flexure. In other instances we find superficial erosions which appear to be the result of epitheiial desquamation and atrophy. Some authors have described a granular variety of chronic sigmoiditis. I have thus far seen but four cases which were really granular in character. The mucous secretion is mostly augmented. Hemorrhages from the inflamed areas are often the result of very slight provocations. Suppuration, when present, is mostly superficial and is characterized by thick and cream-like pus which, as a rule, is not generated abundantly. In some instances, however, as in a case of personal observation reported hereafter, almost incredible amounts of so-called laudable pus are produced and discharged. Thin and watery pus is not a concomitant of uncomplicated chronic sigmoiditis; when present it points strongly to indolent ulcer or to malignant disease.

Pain.—The recurrent attacks of pain in the lower left lateral and median anterior regions of the abdomen—after irregular intervals of comparative ease—are usually the first and only symptom drawing the attention to chronic sigmoiditis. Were it not for the pain most patients with chronic sigmoiditis would not consult a physician. The individual attack of pain is usually of sudden onset. The patient is rarely capable of definitely locating the pain at the beginning of the attack. The painful area, in chronic sigmoiditis, is as a rule decidedly more fluctuating, than that which is the consequence of an inflammatory condition in any other portion of the colon. Pain arising from inflammation of the descending colon, for instance, is pretty well fastened to the seat of the affection and is more or less circumscribed. The peculiar anatomical character of the sigmoid flexure seems to be the main cause to which may be assigned the greater fluctuation of the pain, and the nonaccentuation of the point of tenderness, in chronic sigmoiditis, at the onset of the attack. Again, most mistakes in diagnosis, such as ascribing the pain to an effection of some other abdominal organ, are likely the result of the singular shape of the flexure and of the remarkable and strange anatomical relations it may occupy when it is chronically diseased. When the point of maximum tenderness is once ascertained the exacerbation is generally pretty well under way and the pressure-phenomenon—increased pain on pressing upon, or, on compressing, the area of maximum tenderness—is invariably present.

In chronic inflammations of the cecum, and especially of the appendix, the degree of tenderness and the intensity of the inflammatory process correspond quite closely in many instances. In chronic sigmoiditis this is generally not the case, at least not to that degree. Here a small and superficial lesion in the presence of coprostasis may occasion considerable pain while an ulceration with free evacuation of the pus may give rise to very little tenderness, even upon pressure. When there is an accumulation of feces in the chronically inflamed sigmoid the tenderness, and especially the pressure pain, is often transmitted directly to the back. The backaches of women, in my opinion, are at least as often due to a distended sigmoid as to a distended transverse colon. The burning and tenderness in the buttocks and the very frequent "heavy" and painful left thigh appear to be the result of pressure exerted upon blood-vessels and nerves by the displaced and distended sigmoid. Bodily and mental exertion are apt to bring on an exacerbation and an aggravation of the painful sensations if one of the periodic seizures is already in progress. Riding on horseback and on the bicycle, even sitting for a long time in a certain position, may provoke pain. The immediate irritation of a certain inflammatory area in the emptied sigmoid causes generally much less discomfort to the patient than the external pressure upon the point of maximum tenderness of the non-evacuated flexure. The direct irritation of the inflamed region calls

forth a certain amount of soreness which is more or less circumscribed in extent.

Abdominal distention.—A genuine exacerbation of chronic sigmoiditis is always accompanied by some flatulency and consequently also by some distention not only of the upper portion of the sigmoid but also of the other segments of the colon. The distention, which is mostly quite moderate, may subjectively announce itself in a mere fullness and tightness, while objectively nothing but an augmented area of colonic tympany may be ascertained. In no instance of uncomplicated chronic sigmoiditis did I encounter excessive intraabdominal tension, but the abdominal surface appeared mostly uniformly even and regularly rounded. There is always some resistance of varying degree in the left iliac fossa. This seems to be due to the impacted feces as a rule, but it may be also caused by the indurated area or connective tissue formation in the sigmoid walls, or by adhesions from an antedating perisigmoiditis.

Elevation of temperature.—There is no inflammatory process—even none of a chronic nature in acute exacerbation—which is not accompanied by an elevation of local temperature. This local heat phenomenon may not be sufficiently pronounced to give rise to general pyrexia, but at its seat of production, or near it, its occurrence may usually be ascertained. Thus, during a paroxysmal aggravation of chronic sigmoiditis, the rectal temperature will mostly be found to be somewhat augmented. This may range from 99.5°F. to 103°F. When the rectal temperature is above 100° F. there will be more or less systemic pyrexia. In case the rectal temperature is 1.5°F. or more higher than that of the mouth we very likely have to deal with pus production in the upper rectum, the sigmoid flexure, or the appendical region.

Obstipation.—There exists an innate tendency to obstipation in chronic sigmoiditis. The accumulation of feces in the lower portion of the descending colon and the sigmoid, indeed, seems to stand in more or less close relationship to the recurrence of the individual attacks. Coprostasis undoubtedly acts as an excitant in the chronically affected sigmoid area, but the inflammatory process, in its turn, may give occasion to spasmic or, probably, to atonic conditions of the sigmoid which may stand at the foundation of the constipation. The circumstance that diarrhea frequently supersedes obstipation does not in the least contradict the fact of the inherent tendency for fecal retention in chronic sigmoiditis. Diarrhea following habitual obstipation has to be looked upon as a reactive occurrence, as an effort on the part of the organism to rid itself of foreign material. The watery evacuations in chronic affections of the sigmoid, although ushered in by colicky pains and frequently followed by tenesmus, have a salutary effect. They continue, however, for but limited periods while the inclination to obstipation is prevalent practically all the time.

The obstipation of chronic sigmoiditis may be of the atonic or the spasmic variety. The atonic variety occurs more frequently, but the spasmic type is not uncommon, particularly in males. The atonic constipation may be due to congenital or acquired asthenia of the musculature of the sigmoid, to systemic deterioration, to an atrophy of the mucosa resulting from long-continued catarrhal processes, to degeneration of the splanchnic nerves, and to enteroptosis. Spasmic obstipation is either a reflex phenomenon due to disease of some other organ, or, with greater frequency, it is the result of an exaggerated motor innervation of the muscular structure of the sigmoid manifesting itself in spasmodic contractions of a part of the flexure.

Atonic obstipation of the sigmoid is generally characterized by feces of short cylindrical form and small diameter or by hard and firm fecal nodules, which are occasionally enveloped in a thin layer of transparent mucus. When spasm of the sigmoid is the cause of the retention of fecal matter the fecal cylinders may be somewhat softer and longer, and may appear ribbon-like or flattened on two opposite sides. On other occasions, the evacuations may be entirely scybalous, or may be composed of scybala and unformed masses.

Nervous Phenomena.—It is often difficult to say whether certain neuropathological manifestations are the cause or whether they are the result of the chronic inflammatory process of the sigmoid, or, finally, whether they stand in any relationship at all. We may meet with sensory disturbances, and may notice angioneuroses as local congestions, and erythematous and urticarial exanthema; secretory disorders especially of the stomach, are not uncommon; nerve exhaustion, mainly that variety which has been described by Abrams as splanchnic neurasthenia, is frequently encountered in a more or less pronounced form. Various manifestations of the neuropsychosis hysteria are in evidence in a majority of the instances of chronic sigmoiditis.

Vesicular irritation and leucorrhea.—An irritable bladder is the frequent concomitant of chronic sigmoiditis in males. This is undoubtedly due in most instances to tension and pressure exerted by the intumesced and displaced sigmoid upon the bladder walls. The vesical irritability often ceases after a thorough evacuation of the sigmoid. When the coprostasis extends to the rectum there occurs mostly an undue amount of residual urine, from which the bladder is relieved as soon as the fecal accumulation passes out of the rectum. The irritable condition of the bladder is characterized by a local sensation of burning, tenesmus, and frequent and painful micturition. In some cases we find evidences of vesicular inflammation. Then we have in addition to aforementioned symptoms, which are more pronounced, turbid urine with more or less pus. Cystitis accompanying chronic inflammation of the sigmoid may be due in the first instance to congestion of the mucous membranes of the bladder or to the accumulation in the same of residual urine.

The leucorrheal discharge which is almost invariably an accompanying phenomenon of chronic sigmoiditis in women, is of a more or less spasmodic nature. It appears to be entirely dependent upon the exacerbation of the sigmoidal inflammatory process, arising and declining with them. Up to a certain point, this spasmodic leucorrhea may be looked upon as a manifestation on the part of the nervous system; to the greater extent, however, it seems to be the outcome of the mechanical interference of the diseased sigmoid with the uterus or the adjacent generative organs.* In the intervals, the leucorrheal discharge may persist, assuming, however, a certain degree of latency. It becomes markedly diminished in amount, loses its muco-

*The diseased uterus—on the other hand—may interfere with the function of the sigmoid. The retroverted uterus, for instance, is found in Douglas' pouch tightly agglutinated to the sigmoid after a local perimetritis, and an exudate, due to parametritis, may even diminish the lumen of the flexure temporarily.

purulent character, and appears as a simple catarrhal excretion.

Frequency, Sex, Age.—A chronic inflammatory state of a portion of the sigmoid flexure is by no means a rare occurrence. In my experience, an inflammatory process is of much greater frequency in the sigmoid than in any other segment of the colon. I am of the opinion that a large proportion of cases designated as "chronic colitis" or "chronic enteritis" are in reality instances of chronic sigmoiditis. The extent of sigmoidal distention and displacement may be so great as to *quasi* invite inexact or wrong diagnosis. As a matter of fact, however, any chronic intestinal affection not especially limited to the lower right quadrant of the abdomen, is briefly (and superficially) referred to as "chronic colitis" or "chronic enteritis" by the overwhelming majority of practitioners. Chronic sigmoiditis is an apparently rare affection for the reasons that hitherto but few differentiated between disease of the sigmoid and that of the colon, and that it has as yet not acquired full-fledged citizenship in the works on medicine. Again, the name of the affection is of little importance; it is the extent and location of the lesion which interest us for the sake of the treatment.

The literature concerning chronic sigmoiditis being so scarce it is impossible to give any definite statistical data as to its frequency at this date. I can refer therefore to my own experience only. According to this (which dates back to somewhat over six years, when I began to make a systematic search for sigmoidal involvement in every instance of abdominal disease brought to my attention) *inflammatory processes occur fully as often in the sigmoid flexure as in the cecal and appendical regions.*

I have seen about four times as many cases of chronic sigmoidis in females as in males. All the males in whom I diagnosed the affection were thin and undernourished individuals. The women who exhibited sigmoidal inflammation were generally in a better state of nutrition. The prevalence of the affection in woman must be consequential to gestation, and to the frequent occurrence of general enteroptosis, more especially coloptosis and sigmoidoptosis, and their inevitable concomitant, obstipation.

Almost all the instances of chronic sigmoiditis, which came under my observation, occurred in individuals over thirty years of age; in but a few cases the clinical picture was fully developed between the second and third decennary of life. A majority of the cases started around the thirty-fourth or thirty-fifth year. In a few instances the affection had not appeared before the fifth decennary of life. When first brought to my attention the symptom-complex had existed in the various instances for from a few months to fourteen years.

Course.—The affection runs an exceedingly chronic course. It may be ushered in as an acute sigmoiditis; however, as the symptom-complex develops but gradually we may assume that it is not necessarily in etiological relationship to the acute variety. Chronic inflammatory processes of the sigmoid are characterized by irregularly occurring exacerbations of the symptoms, by remissions and intermissions. The exacerbation lasts usually from twelve to thirty-six hours, the stage of abatement of the acute symptoms from three days to two weeks, and the intermission—the pain-free period—is of most irregular duration. Rational management of the condition should bring about some improvement—a functional improvement so to say—in every instance. A complete amelioration is certainly possible in all those instances where the inflammatory process is superficial and limited in area. Many of the graver forms of inflammation are undoubtedly amenable by proper surgical treatment. The subsidence or cessation of the systemic phenomena ensues runs generally parallel with the amelioration of the local condition.

Diagnosis.—Chronic sigmoiditis is readily recognized by its symptomatology, and particularly by the direct inspection of the affected area with the sigmoidoscope. In every case of recurrent pain in the lower left quadrant of the abdomen, increasing upon pressure, and in the presence of more or less acute aching in the buttocks and the left thigh, and habitual constipation, chronic sigmoiditis should be thought of. The history of the case, the rather sudden onset of the individual attack, and the obstipation facilitate the diagnosis of chronic sigmoiditis. Inspection reveals in almost every instance some abdominal distention in the vicinity of the affected area, which is more pronounced in lean

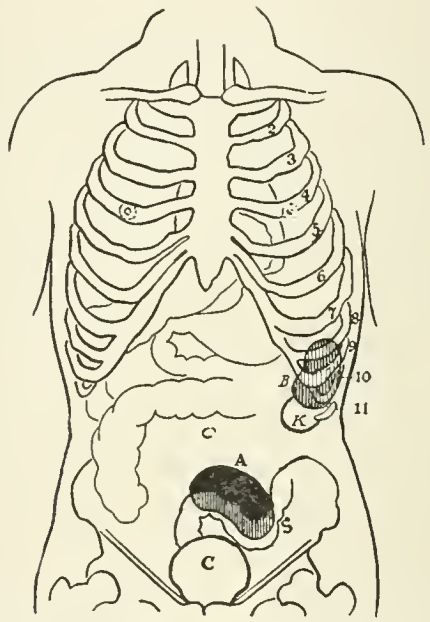

FIG. 1.—One of the author's cases of splenoptosis. A, splenic tumor; B, spleen after retraction; C, bladder; K, kidney. S, sigmoid flexure. (*From the International Journal of Surgery.*)

persons. The abdominal distention is best noticed when the eye of the examiner, who is standing at the head of the reclining patient, can travel down the latter's body. Percussion, which I *always* perform with hammer and pleximeter, elicits the deadened sound to which Traube has already drawn attention, and the tympany, due to gaseous inflation, in the upper portion of the involved colonic segment. Palpation increases the sensitiveness of the affected area and may hence serve as a means for its localization. Schilling[2] has given some valuable points on the palpation of the sigmoid flexure. Auscultation is of no assistance in determining the seat of the pathological process.

Differential Diagnosis.—The principal abnormal states from which chronic sigmoiditis must be distinguished are neoplasms, adhesions, prolapse of the left kidney, wandering spleen, and the diseases of the female internal organs of generation. The spleen, in exceptional cases, may descend into the pelvis and come into close contact with the sigmoid flexure as shown in the accompanying drawing of one of the author's cases of splenoptosis.[3]

By a careful physical examination—even without sigmoidoscopic inspection—the various affections with which chronic sigmoiditis may be confounded, can be readily excluded as a rule. Of course, when one or the other of these affections concurs with chronic sigmoiditis a discriminating diagnosis is more difficult to arrive at. In all pertaining instances the employment of the sigmoidoscope is imperative.

The following instances of chronic sigmoiditis are a few of those which have come under my observation:

Case 1.—The true nature of this instance of chronic sigmoiditis—the first case of the affection ever brought to my attention—was only recognized by me some years after it came under my observation. It must be remembered that in 1894, the year when the case was first seen by me, we did not know anything at all about chronic sigmoiditis. Besides, the case was not of the rather frequent and typical catarrhal form, but one of the much rarer suppurative variety.

In the night of February 12-13, 1894, I was hurriedly summoned to Mrs. Anna D., thirty-four years old, a native of the United States, the mother of one child. The patient appeared to be in great agony, and her husband told me that she had had a number of similar attacks before, that she was under treatment for uterine disease for some years, and that nothing but hypodermics of morphine would afford relief of the acute pain. She had a temperature of 103.5° F. (taken by the mouth), which, as on previous similar occasions, was preceded by a chill. The abdominal examination revealed pronounced tenderness in the hypogastric and left inguinal regions. Palpation proved unsatisfactory on account of the insufficient pressure which could be exerted. A diagnosis was not attempted that night. Morphine was introduced hypodermically, and soothing applications were ordered to be applied upon the abdomen.

Four days later, when the acute symptoms had abated, the following history was elicited from the patient. For three years previously she had periodic attacks of severe cramp-like pains in the left lower abdomen, which always followed constipation of some days' duration. The pains would be felt in the back and would often extend down the thighs. The attacks would come on at irregular intervals, and were always ushered in with chills, after which a rise in temperature would set in. Unless morphine was administered and free evacuations secured the pain would last for some days. There was a vaginal discharge all the time, which became more profuse and of very offensive odor during the attacks. The attacks would not, as a rule, concur with the menstrual periods. In the intervals the feces would cause more or less trouble, and would invariably be discharged together with goodly amounts of what was considered yellowish pus. The excretion of pus would also frequently ensue on going to stool when defecation did not take place. The patient had consulted a number of physicians, who, it seemed, were unanimously of the opinion that the attacks were due to disease of the uterus or its appendages, and that the apparent pus came from some part of the generative system opening through a fistula into the upper part of the rectum. A thorough examination of the rectum made by me did not show a fistulous opening, but pointed out that the pus came from beyond the rectal ampulla. A special examination of the sexual organs by a gynecological expert revealed a chronic endometrial inflammatory process and a slight bilateral salpingo-oophoritis. The source of the pus, which apparently traversed some part of the intestinal canal, could not be determined.

The patient, strongly objecting to an exploratory laparotomy, as she felt quite comfortable in the intervals, remained under my care for a long time. I thus had occasion to observe and study numerous attacks, all of which resembled the one described in the foregoing. There would be pain in the abdomen and the sacral region, the obstipation, the chill, the fever, and the cessation of the excretion of suppurative material. After a while I came to the conclusion that the retention of the pus seemed to stand in close relationship to the production of the chill and the subsequent temperature elevation. So long as the discharge continued there ensued no temperature variation. A careful inquiry into the nature of the discharge showed the following:

Amount of discharge in twenty-four hours (average of four consecutive days), estimated, 25 cc.; color, light yellowish (Vogel's scale of urine tints No. 2); odor, none; consistency, creamy; reaction, slightly alkaline; water, 84.3 per cent.; solids, 15.7 per cent.; fats, 1.8 per cent.

The microscope showed pus corpuscles in enormous and erythrocytes in moderate amounts, also epithelia and goodly numbers of young leucocytes (mucous and lymph corpuscles). The microchemical reaction left no doubt as to the pus character of the discharge.

If the case had not been of such decided chronic nature (and if the patient had shown pronounced pyemic symptoms) the origin of the pus could have been assigned to a paraintestinal suppuration breaking through and into the colon. The pus was pure and was discharged either alone or but superficially adhering to the outside of the hardened feces. A real admixture of the pus with the feces was never observed. Floccules of pus, grayish white and resembling small mucous flocks as they are occasionally seen in chronic inflammatory disease of the small intestines, were hardly ever met with. Pieces of membranes, or other components of the pathological excretion denoting membranous catarrh of the intestines, could not be distinguished.

The abundance of the pus excretion and the perfect morphological condition of the pus corpuscles pointed to a suppurative process in the lower segments of the colon. Were the pus cells derived from an ulcerative condition in the small intestine, or had they taken their origin in the cecum, they would have been disintegrated—by digestion and putrefaction—to such an extent that but small floccules, undeterminable as pus, could have passed out of the anus.

In the course of time the attacks became more frequent, and in consequence thereof the patient grew weaker and became morose. She had consulted a number of gynecologists and a proctologist in the meantime—neither, however, having arrived at a proper understanding of the pathological condition. In 1898, after an attack, when the temperature remained between 101.5° and 103° F. for about one week, I insisted upon the exploratory laparotomy, and if possible, a curative operation. The abdominal section was performed by Dr. Charles K. Bridden, at the Presbyterian Hospital. I do not remember all the details of the operation, but, although the appendix and some of the uterine appendages were removed for minor disease, the seat of the pus formation, in spite of a thorough search for it, could not be detected. The operation

availed nothing whatsoever so far as the attacks and the pus excretion were concerned.

Early in 1899 I succeeded in definitely locating the lesion in the middle and lower portion of the sigmoid flexure by means of Trousseau sounds and a long Kelly endoscope. The olive point of the sound which was introduced through the endoscope could be clearly felt through the abdomen, and the point of maximum tenderness could be located in the sigmoid flexure without the shadow of a doubt. On the withdrawal of the sound the endoscopic tube was introduced further and I could see the oozing of the pus from the exposed and inflamed areolar tissue of the sigmoid. For this cellulitic state local treatment was advised, which soon brought about some relief. On account of a four months' absence from town the patient drifted from my observation.

Case 2.—Mrs. Fannie F., mother of one child, came first under my observation in 1899 when she was 63 years old. She had irregular periodic attacks of pain in the lower left abdomen, radiating toward and beyond the median line, recurring every week or second week and lasting, on the average, for about two days. Obstipation and subsequent compensatory diarrhea, with more or less discharge of mucus, were the rule. The temperature was always increased, varying from 99° F. to 100° F. in the mouth, and from 100° F. to 102.5° F. in the rectum. Painful sensations of apparent neuralgic character in both thighs and buttocks were invariably present. She also experienced a good deal of vesical tenesmus during and after the seizures, and the urine showed the characteristics of a slight inflammatory state of the bladder. The patient had undergone treatment at the hands of a number of practitioners. She had been treated for chronic appendicitis, for enteritis, and for mucous colitis. In spite of all medication, the attacks had become more frequent of late.

A local examination during an interval revealed a number of thrombotic hemorrhoids and an apparently chronic or subacute congestion of the rectal mucosa. A flexible sound brought through the endoscope into the lower portion of the sigmoid flexure, disclosed therein a pronounced state of tenderness. The case was therefore treated as one of sigmoid inflammation. Local treatment, by means of irrigation, was instituted. The attacks soon became less violent and diminished in frequency. During 1900 the patient had five attacks, in 1901 also five attacks, in 1902 three attacks, in 1903 six attacks, in 1904 four attacks, in 1905 no attack, in 1906 one attack. Numerous examinations made between 1900 and 1904 disclosed the much improved condition of the sigmoidal mucosa.

Case 3.—Mrs. Kate E., 43 years old, no children, was referred to me on January 26, 1901. Patient gave a history of manifold ills and aches extending over a period of more than twenty years. For the past ten years she had had on a few occasions fecal impaction of very firm consistency which could be broken up and removed with the greatest difficulty only. She was obstipated practically all the time, and the various physicians who attended her had in vain tried to overcome the intestinal atony. Every now and then she had an attack of severe pain in the lower left side of the abdomen increasing upon pressure and concurring with sigmoidal and colonic inflation, aching pain in the lumbar region and the buttocks, and neuralgic manifestations in the left ovary and thigh. There was always an elevation of rectal temperature during and after an attack. In one instance the rectal temperature, varying between 101.5° and 102.5° F., continued for more than two weeks after the attack. Severe headaches and hysterical manifestations completed the clinical picture. Endoscopic examinations of the sigmoid showed a great deal of granulation tissue in all parts of the mucosa. There were also raw spots and some bloody serum. The patient was put upon constitutional and local treatment. A course of Fleiner's oil cure, continued for about ten weeks, finally overcame the lethargy of the lower bowel.

Case 4.—Mrs. Lillian C., 30 years old, mother of two children, was referred to me on January 30, 1903. The patient was very lean, weak, and nervous. She suffered from habitual obstipation, and had the recurrent attacks with all the earmarks peculiar to chronic sigmoiditis. There was the pain in the left inguinal fossa extending to the umbilical region, becoming intensified upon pressure; the pain in the back, buttocks and left thigh, the elevation of rectal temperature during and after the seizures, the spasmodic leucorrhea, and occasionally colonic mucus containing once in a while some streaks of blood. Abnormal phenomena on the part of the nervous system were also not wanting. An examination of the electric sigmoidoscope confirmed the diagnosis of chronic inflammation of the sigmoid flexure. The proper treatment, which was principally a local one, has in the course of time brought about a complete restoration of the patient, whose weight, vigor, and resistance have materially increased.

Case 5.—Mrs. Esther B., 33 years old, no children, consulted me on April 23, 24, and 25, 1905. For a year and a half she is suffering with pains in the left side extending from the region of the bladder to the buttocks. The pains usually occur once or twice weekly, and invariably concur with obstipation. The pain-free interval occasionally lasts for one or two and even three weeks. The pain is of a pressing nature and increases when manipulating the affected area. The point of maximum tenderness is referred to as being situated in the left iliac fossa. The pain produces a tired feeling in the left leg and continues to be quite severe for three or four hours. Frequently a burning sensation in the bladder and frequent micturition are in evidence. A moderate fever generally accompanies the attacks. Intestinal mucus and some shreds of membrane have been noticed once in a while. The physical examination shows the sound condition of the genital organs, and the limitation of the intestinal inflammation to the sigmoidal segment.

Case 6.—Francis H. J., 35 years old, native of the United States, a lawyer by occupation, was referred to me for the diagnosis of his condition on Sept. 25, 1905. The symptom which troubled the patient more than any other was severe headache recurring at irregular periods, but generally once a week, for which all kinds of treatment at the hands of general practitioners, neurologists, and ophthalmologists had been without avail. Hand in hand with the headache there always occurred obstipation and pain in the left lower abdomen, the lumbar region, the buttocks, and the left thigh. Vesical irritation was also not missing. My first examination of the patient was made on a day of an attack. He had vomited a number of times in the morning, was very weak, and complained of intense migraine. The rectal temperature was 103.2° F., pulse frequency 110, and the pressure of the radial arteries equivalent to 120 mg. of mercury.

The bowels had not moved for three days. There was a distinct maximum area of tenderness in the

left iliac region, which could be referred to the sigmoid flexure. This, as well as the descending colon, could be readily palpated as they were loaded and dilated with hardened feces. The patient complained of heavy pressure pains in the lumbar region and of numbness in both legs. The pupils appeared rather contracted, co-ordination was impaired, and the various reflexes were exaggerated. The urine exhibited a specific gravity of 1015, and no pathological constituents of any sort.

The symptom-complex offered by the patient was one which is characteristic of intestinal toxicosis, or of autointoxication originating in the intestinal tract. The patient was treated according to the rules laid down in my work on autointoxication.[4] On the day of the second examination, three days later, the entire syndrome had disappeared, but there was present some diarrhea and tenesmus. The latter appeared of sigmoidal origin. The rectosigmoidal examination, made in the knee-chest posture, disclosed external hemorrhoids, a spongy condition of the rectal mucosa, and a profound granular inflammation of the entire sigmoid flexure.

Case 7.—James D., 37 years old, native of United States, a coachman, came under my observation on February 14, 1905, giving the following history: Every few days, when driving in the late afternoon, he would get a cramp-like pain in the abdomen, which forced him to draw up his knees and sit on his right buttock. The pain would increase when he would stretch himself out or was lying flat on his bed, and would make itself evident all over the abdomen and the lumbar region. The thighs, especially the left, would often feel as being compressed by a tourniquet. Obstipation and meteorism would prevail practically all the time. There would occur occasionally a small discharge of mucus from the rectum, together with that of the feces, but not intermingled with them. The abdominal pain would also be felt in the bladder, which, becoming irritable, would cause a frequent desire to micturate. The attacks would be ushered in with a chill, as a rule, and the patient would be feverish for a day or two. He would take all kinds of cathartics and laxatives, and would increase the dose when they had failed to act sufficiently. He was examined by some physicians, who pronounced his case one of chronic appendicitis, advising an operation.

The abdominal examination revealed three distinct points of maximum tenderness: Over the hepatic and the spleenic flexures of the colon and in the left iliac fossa. In the latter there was marked rigidity. The entire colon seemed to be full and inflated. A large dose of castor oil was ordered to be taken in order to procure a complete evacuation of the bowels. The examination on the following day elicited rigidity of the abdominal muscles, tympanitis over the area of the cecum and the transverse colon, much exaggerated gurgling sounds in the cecum, an area of maximum tenderness increasing upon manipulation in the left iliac fossa, and excruciating pain in the anterior rectum on palpation. The acute symptoms, including the obstipation, subsided after about two days, the treatment consisting merely in the administration of atropine.

The inspection of the sigmoid flexure with the endoscope, made a week later, causing no inconvenience in the rectum, evinced a general inflammatory condition of the sigmoid, including minute pus foci and streaks of apparently raw surface. Abdominal palpation over the sigmoidal area, performed while the endoscope was in situ, demonstrated the presence of a circumscribed but quite extensive area of tenderness on all sides of the instrument. This fact was deemed rather suggestive of concurring chronic involvement of the peritoneum, with possible adhesions. The case was hence diagnosed as one of chronic sigmoiditis complicated by perisigmoiditis. Since the institution of treatment for this condition, the patient had but one recurrence of the attacks (Feb. 1, 1907).

Case 8.—Mrs. Betty L., 53 years old, born in Russia, mother of four children, came under my observation on Feb. 13, 1907. She complained of painful seizures in the left hypochondrium, which would supervene at irregular intervals, occasionally twice a week, but mostly weekly or biweekly. The attacks would come suddenly, but would be preceded by obstipation, which always prevailed more or less. The pains would be dragging or pressing in character and would radiate toward the back, the groin, and the genital organs. Occasionally there would be some mucus in the stools. She had been treated for prolapsed left kidney, for colitis, and for uterine retroflexion. The physical examination on a pain-free day elicited the condition of general enteroptosis, including the prolapse of the stomach, the transverse colon, both kidneys and the uterus. On percussion there was a tympanic note over the transverse colon, but a pronounced, deadened sound over the hepatic as well as the spleenic flexure of the colon. Traube's phenomenon was present in the left iliac fossa. Palpation demonstrated the presence of hardened fecal material in the descending colon and the sigmoid flexure, and an area of maximum tenderness in the left inguinal region. There was no tenderness on the right side nor over the bladder or the internal organs of generation. The rectal temperature was 99.6° F. There were some external and internal hemorrhoids. The sigmoidal mucosa appeared in a state of congestion and was quite tender throughout. The endosigmoidal tenderness corresponded exactly with the area of maximum tenderness in the left inguinal region, which was elicited from without. The case was diagnosed and treated as one of uncomplicated chronic sigmoiditis.

General Conclusions.—The eight instances of chronic sigmoiditis, the brief histories of which are recounted in the foregoing, form about the sixth part of all the cases of that affection which have come under my observation. Naturally, extent and intensity of the inflammatory processes were of manifold degree in the various instances. That an inflammatory condition may be limited to the sigmoid flexure there is no question. That such an inflammatory condition may be idiopathic, at least in a proportion of cases, we have to assume on logical grounds. However, we will not be far out of the way when we maintain that a goodly number of the pertaining instances are deuteropathic in character; that they are, in other words, the consequence of a pre-existing condition. The direct local condition predisposing to inflammation of the sigmoidal mucosa is habitual obstipation and long-continued drug-catharsis, the more mediate cause acting as predisponent for sigmoiditis being an adequate or perverse nerve impulse in the descending and especially in the sigmoidal segments, of the colon.

In every instance of chronic sigmoiditis which came to my notice, there prevailed obstipation or a tendency thereto, and the characteristic lethargy of the large intestine, which is directly attributable to

the customary ingestion of purgatives. Stagnation of the feces occurs mostly in the lower portion of the descending colon, and in the sigmoid flexure the peculiar anatomy of which virtually invites the retention of feculent material. Inflammatory processes of the colonic and sigmoidal mucosa may thus be set up readily to some extent, by mechanical injury on the part of the accumulated excrementitious substances, to some extent by chemical irritation of the products of secondary fermentation evolved from the impacted feces.

Intestinal spasm, atony, or paresis, by giving occasion to obstipation, may be the more remote causes of chronic inflammatory processes of the sigmoid flexure. The great majority of all intestinal affections which are due to insufficient or perverse innervation arise in the sigmoid. An initial intestinal spasm is almost in every instance confined to the sigmoid; intestinal atony or paresis, as a rule, starts in the sigmoid; seventy per cent. of all cases of volvulus—due primarily in almost every instance to fecal impaction, and induced forced peristalsis, that is, perverse innervation—occur in the sigmoid flexure.

Of course, chronic sigmoiditis may be associated with numerous concomitants and complications. Its occurrence, in fact, favors the production of other, especially functional, disturbances of the alimentary canal. Functional disorders of the cecum, for instance, it seems to me, are often due to a chronic pathological condition of the sigmoid. The synchronous occurrence of cecal derangement and the syndrome of chronic sigmoiditis often present the clinical picture of chronic appendicitis. Again, we know that in the etiology of appendicitis itself, chronic obstipation (and consequently sigmoidal disease) plays an important rôle. Furthermore, perisigmoiditis may be due to the same cause which gives occasion to endosigmoiditis, or it may be the direct consequence of the latter, and inflammatory processes in other parts of the peritoneum may be engendered by chronic sigmoiditis or its most frequent immediate precursor—obstipation.

Having abundant evidence that the vast majority of instances of colitis are limited to the extreme lower portion of the colon, the sigmoid flexure, that obstipation and the aforementioned neuroses of the intestines concern, at the outset at least, virtually only the lowest portion of the colon, we are at loss to understand why the present day treatment of the affections occurring in that region consists almost exclusively in the ingestion of drugs which have to traverse about thirty feet of the alimentary tract before they reach the seat of the lesion. Small wonder, therefore, if the target is not hit at that distance, if the drug loses its efficacy during its passage from one end of the alimentary tube to the other, if its effects are uncertain and ephemeral, and if it even contributes to the aggravation or the perpetuation of the local lesion. We do not treat a local affection of the nose by the exclusive internal administration of medicines, and there is no reason whatsoever why affections in those parts of the lower colon which are accessible to local treatment should not receive the benefit of the latter in addition to the proper causal and constitutional management.

Treatment.—The *causal treatment* of chronic sigmoiditis consists in the regulation of the functional activity of the sigmoid flexure. In my experience, sigmoidal spasm (and therefore many cases of intestinal occlusion) is readily amenable to atropine in practically every instance. To this end, the alkaloid should be given hypodermically, in doses of 0.0006 gram (1/100 gr.), which should be repeated until relaxation of the affected parts has ensued. When the spasm is less pronounced, but occurs on the slightest provocation—a factor which stands at the foundation of so-called spasmic obstipation—a mild nervine-narcotic, administered by the mouth or in the form of suppositories, will generally give the best results. Lupulin is probably the most effective, and at the same time an innocent, enteric nervine-sedative.[5] Enterospasm of this nature is often permanently overcome by the long-continued administration of lupulin in daily doses of from 2 to 4 grams. Lupulin, in the following combination, may be found of service in the motor neuroses of the sigmoidal segment of the colon.

℞ Lupulini .....
Strontii bromidi ....aa 0.15
Ft. caps. d. t. dos. No. L.
Sig. Two capsules 3-5 times a day.

℞ Lupulini 0.3
Pulvis ipecacuanhae 0.02
Ft. caps. d. t. dos. No. XX.
Sig. One capsule 4-6 times a day.

Strychnine and kindred tonic medication have in my hands proved very inefficient in overcoming intestinal atony of any degree. Drugs of the class of lupulin have proved in my experience decidedly more valuable in the treatment of intestinal motor insufficiency. In all sigmoidal neuroses I have often prescribed to advantage lupulin in the form of suppositories (in hollow glycerogelatin cones if possible), which I ordered to be introduced as high as possible into the rectum. However, medicines are the least effective remedial agents which are at our disposal in the management of long-continued sigmoidal lethargy. Regulation of the diet is the foremost curative factor. A regimen in which the proteids preponderate leaves very little residual matter in the intestines and tends therefore to obstipation. One, in which the carbohydrates occur in abundance, is productive of flatulence and intestinal hyperfermentation and therefore of mucosal irritation. The diet, best suited for sigmoidal lethargy, is one in which green vegetables like spinach, lettuce, savoy cabbage, string beans, and absorbable fats with comparatively high melting point, like the yolk of the egg, predominate. In the ratio in which the motor mechanism improves may the amount of green vegetables and fats be reduced, to be replaced by proteids and carbohydrates. The sugars are the carbohydrates producing the least digestive difficulty.

However, it is best to defer the ingestion of starches for as long a time as possible; when the functional activity of the sigmoid has been definitely re-established they may be permitted in small amounts. No matter how well individuals who have been subject to intestinal motor insufficiency feel at the time, starchy foods should always be partaken of by them sparingly. Yolks, and in a measure also, the green vegetables, should compensate for the loss of nutritive elements.

The next important means in overcoming sigmoidal atony is exercise, active as well as passive. Of course, the active exercise must not exhaust the patient, as overexertion would not only impede his improvement, but would probably cause an aggravation of the atonic state. Walking is a good mode of exercise, but swimming is greatly more efficient as a rule. Calisthenics, promoting the vigor of the abdominal organs, are very useful. A gymnastic

exercise which seems well adapted for the reduction of intestinal motor insufficiency in general and sigmoidal lethargy in particular, is the following: The patient, standing, raises the bent leg so that the knee comes to the level of the hip, and after holding it in that position for a few seconds, suddenly jerks it forward forcibly. This exercise is executed by alternating with the two legs in the manner that the left leg performs it always twice in succession and the right leg but once. Thirty of these individual exercises, twenty with the left leg and ten with the right leg, should be carried out from three to ten times during each day for a more or less protracted period. Breathing exercises, developing abdominal breathing, are imperative in the treatment of sigmoidal motor insufficiency. They should go hand in hand with the other exercises.

Of the passive exercises, massage, electrical and vibratory massage, and the Zander mechanical movements, in my experience, have proved to be grossly overrated devices in the management of sigmoidal lethargy. By far the best results in the way of passive exercise I have obtained with a strong faradic-sinusoidal current. This combination current is to be applied by means of sponge electrodes, one pole in the left iliac fossa or on the left thigh, the other either near the splenic or the hepatic flexure of the colon. The secret of success when employing this form of electricity for the treatment of deficient sigmoidal motor mechanism depends on the one hand on the proper placing of the electrodes and on the other, on the length of time the affected area is subjected to the current. The applications, of which each must occupy at least one hour, should be made daily, if possible. Three or four weeks' continuous treatment will mostly show the desired results.

Hydrotherapeutic procedures often render efficient service in the treatment of sigmoidal lethargy. Cold sitz baths, the cold abdominal pack, and the Scotch douche should be given a trial in conjunction with the other physical means. When the sigmoidal lethargy goes hand in hand with a relaxed and elongated state of the muscle fibres of the sigmoid, sigmoidal atony—when, in other words, functional disturbance concurs with structural changes, rest and other measures employed in the treatment of enteroptosis, should be resorted to. Rose's belt, with a number of additional supporting straps of zinc oxide plaster in the left iliac fossa, will yield very satisfactory results as long as the patient is kept on his back. Later on a well-fitting abdominal supporter, as the one devised by me,[9] with special upbearing pads in the inguinal and sigmoidal regions, should be worn for an indefinite period.

For the *pain* of an acute exacerbation of chronic sigmoiditis opium, or any of its derivatives, for well-known reasons, should never be prescribed. Usually the evacuation of the bowels is promptly followed by the subsidence of the more intense pains. Hot applications and counterirritants may be applied to the abdomen, the buttocks and the thighs. In case the painful sensations continue, suppositories containing belladonna, the extract or powdered leaves, should be inserted into the rectum as high up as possible. If tenesmus is present, it is advisable to add lupulin in gram doses to the suppository which should have for its base a glycerogelatinous mass.

The *local treatment* is imperative in the rational management of chronic sigmoiditis. The success of the local treatment depends in a certain measure upon the transitory quiescence of the sigmoid flexure. Such a state of repose of the sigmoid, as we have seen, is the rule when it is chronically inflamed. Of course, an active intestinal peristalsis should be reduced as much as possible during the time of local treatment. However, a complete suppression of the peristalsis, as is advocated by many clinicians in certain acute processes, is neither called for nor possible to carry through without producing additional injury. Opiates are here again entirely out of place. Belladonna, lupulin, valerian, viburnum opulus or prunifolium, bromides, chloral hydrate, cannabis indica, and similar agents—when small amounts of liquid and solid ingesta are taken—induce a transitory state of additional sigmoidal inactivity sufficing for our purposes.

Before local treatment is applied the sigmoid flexure must be entirely evacuated and cleaned. There is nothing that accomplishes this end better than a high enema of warm soap suds. In many of the ordinary cases the local treatment may be applied by means of sigmoidal irrigation through a 50 cm. (18 inch) soft rectal tube. Of course, care should be taken that the tube becomes properly engaged in the sigmoid, but it is not essential that it be pushed into it for more than 10 cm., that, in other words, the tube be inserted for more than 30 cm. (12 inches) measured from the anus. For soothing the irritated or inflamed surface of the mucosa I am in the habit of ordering irrigations with freshly made infusions of chamomile flowers or with infusions of sage (sage, 15 grams, water, boiling, 500 cc.). The compound infusion of sage, warmed to about 110° F., the formula of which is appended, serves as an excellent emollient and very mild astringent.

℞ Sage ..... 15 grams
Hyssop ..... 15 grams
Borax ..... 2 grams
Water, boiling ..... 500 cc.

Infuse the drugs with the water, and dissolve the borax in the colature.

The healing process is undoubtedly hastened by irrigation with very mild astringents. For this purpose, borax alone in 2 per cent. solution, or boric acid in the same strength, or zinc sulphate 1:1000 H_2O, or lead acetate 2:1000 H_2O, or aluminum acetotartrate 10:1000 H_2O, may be freely employed.

All other local treatment should be applied through an ordinary rectoscopic tube of about 25 cm. (10 inches) in length, or in inexceptional instances, through the much longer sigmoidoscopic tube. I prefer the smaller tube, firstly, because it is long enough to serve as a guide for the flexible applicator which is gently pushed to the diseased area in the sigmoid, and, secondly, because the reflected light or the electric headlight can be employed to greater advantage with a short than with a long tube. Protective and healing agents other than bismuth or calcium carbonate, which may be injected as an emulsion through a stiff catheter, should be applied directly to the inflamed mucosa. It is always best to try first the milder protectives and astringents before resorting to agents like silver nitrate or tannic acid. The strong astringents, it is true, call forth reduction of the inflammatory phenomena, as pain, heat, redness, swelling, and hypersecretion, in many instances, but they produce a leathery mucosa which cannot functionate properly.

As the disappearance of the symptoms of inflammation is not synonymous with the reestablishment of a physiological state, and as the strong astringents give rise to an abnormal condition of the sig-

moidal mucosa, it is invariably advisable to wait with their administration until the weaker agents have proved inefficient. Good protective applications which are slightly astringent and have decided analgesic and antiseptic action are the following pastes:

℞ Menthol .....2.5 grams
Oil Eucalyptus .....20. grams
Bismuth subnitrate ..12. grams
Glycerin .....15. grams
Gum tragacanth / Water } q.s. ad 60. grams

℞ Oil Eucalyptus .....30 grams
Bismuth subnitrate....30 grams
Oil olive .....15 grams
Powdered gum acacia.....
Make emulsion.
Water.enough to make 60 grams

These pastes will not deteriorate and are always ready for use.

The organic silver compounds I classify among the milder astringents; they may be used in proper solutions as local applications. If the case cannot be successfully treated without taking recourse to tannic acid or silver nitrate, they should be employed as direct topical applications and never in the form of irrigations.

There are, of course, a great number of agents which may be of use in the local treatment of sigmoiditis. In their employment we must be guided by the same principles which underlie the treatment of mucous membranes in other parts of the body, viz., not to replace one abnormal state by another, but to bring about the physiological activity of the diseased tissue without injuring the structural or functional conditions of the adjacent areas. Deep-seated suppurative conditions of the sigmoid and certain forms of chronic sigmoiditis associated with perisigmoiditis, perisigmoidal abscess, adhesions, or other complications involving the structure of neighboring organs, do not belong in the realm of the internist, but demand surgical interference. The earlier the nature of such cases is recognized and the earlier they are operated upon, the more chance there will be for ultimate recovery. If after abatement of an exacerbation of chronic sigmoiditis and in the absence of any other disease, an elevation of temperature has continued for two or three weeks together with chills, emaciation, anemia, and malaise, we very likely have to deal with a suppurative process in the sigmoidal structure or its vicinity requiring operation.

The treatment of all uncomplicated cases of chronic sigmoiditis, however, belongs unquestionably to the general practitioner.

CARDIAC HYDROTHORAX.

REPORT OF A CASE ASPIRATED 311 TIMES.*

BY W. TRAVIS GIBB, B.S., M.D.,

NEW YORK.

VISITING SURGEON, WORKHOUSE, ALMSHOUSE AND PENITENTIARY HOSPITALS; CONSULTING SURGEON KING'S COUNTY PENITENTIARY HOSPITAL.

WHILE the case I have to report belongs to a class whose occurrence is too frequent to call for any special attention, it is particularly interesting on account of the large number of times the man's chest was aspirated and the enormous quantity of serum withdrawn in a comparatively short space of time.

Hydrothorax of cardiac origin is a condition too well known to require a lengthy discussion of its morbid anatomy, etiology, symptomatology, etc., at this time. Suffice it to say that it is an effusion of serum into the pleural cavity, not due to a disease of the pleuræ. It is a symptom resulting from a variety of causes which produce physical exosmosis of the blood serum. It is merely a dropsy of the pleural cavities. These cavities become reservoirs of serum just as the interstitial tissues of the body become waterlogged in the same diseases. It is never idiopathic, but invariably accompanies some disease or condition which is characterized by an abnormally increased venous pressure following dilatation of the right heart after compensatory hypertrophy has reached its limit and the heart yields to the backward current of blood. It is the result mainly of resistance to the free circulation of the blood through the vascular bases of the pleural membrane. There is no lesion of the pleura itself, but the pleura and subpleural connective tissues are swollen and thickened by maceration in the serum.

Hydrothorax more frequently accompanies valvular diseases of the heart and chronic nephritis, and when due to these causes it is usually bilateral. It is occasionally caused by pressure upon the venous trunks and upon the thoracic duct due to intrathoracic tumors, aneurysms, emphysema or sclerosis of the lung, and then it is usually unilateral and occurs without general dropsy.

The patient, a physician not in active practice, was 46 years of age, had always led a fairly active, more or less outdoor life, and while not in the most robust health, had never had any serious illness. His previous habits as to alcohol and tobacco were fairly good, but during this illness he stopped their use entirely. While a medical student, at the age of twenty, he had discovered that his urine contained a small percentage of albumin. He did not know the cause of this condition, when it first made its appearance, or whether it had been constantly present since that time, for he never had had his urine examined, and owing to the fact that he knew it had contained albumin he never applied for life insurance, fearing rejection. When twenty-five years of age he contracted syphilis, for which he was treated for about three months, until all the secondary manifestations had disappeared, when specific treatment was discontinued. As far as he knew he never had any of the ordinary tertiary lesions of the disease. He married shortly after this, and although his wife was never pregnant she never developed any specific lesion. I removed her appendix and right ovary and tube in 1903 for acute inflammatory conditions. His family history was

*Read before the New York County Medical Society, April 22, 1907.

excellent. His parents and grandparents were very long-lived. One grandmother died at the age of 104 and his mother is still living at 87 or 88, and is in good health.

When I first examined him in 1903 I found his heart greatly hypertrophied with obstructive murmurs at both the mitral and aortic valves. He had no edema and only suffered inconvenience from dyspnea and cardiac irregularity on severe or prolonged exertion. There was no fluid in his chest or abdomen at that time. His urine contained about .5 per cent. of albumin and a few hyaline casts with a normal urea percentage. During the summers of 1903 and 1904 the patient sailed a small yacht, and on several occasions, especially in 1904, he was in considerable danger and was compelled to overexert himself. Shortly after a particularly severe exertion, when his boat went ashore in a storm, dyspnea on the slightest exertion began to develop, his feet and legs became edematous, and I found a small amount of fluid in both pleural cavities. Regurgitant murmurs at the aortic and mitral orifices were noticed and he was unable to sleep lying down. His condition became worse very rapidly, the fluid in his chest increased, ascites appeared, and the edema reached his buttocks. A diagnosis of specific aortitis had been made and the iodides had been pushed to the point of tolerance without the slightest benefit. His condition became so distressing from dyspnea and edema that on October 15, 1904, I aspirated and withdrew 80 ounces of ordinary serum from his left pleural cavity, and the following day fifty ounces were removed from his right side.

With the first aspiration his dyspnea, edema, and cardiac irregularity decreased. It was soon noticed that there was a marked decrease in the amount of urine he was secreting, and during the rest of his life he averaged but 12 to 18 ounces daily. Frequent analyses of his urine showed little or no variation. Specific gravity 1.025, strongly acid, color very dark, urea 2.5 to 3 per cent., chlorides increased, albumin .7 per cent. Hyaline, granulohyaline and pure granular casts were present, together with epithelium from the pelvis of the kidneys and from the bladder. The uranalysis indicated that he had a chronic parenchymatous nephritis.

The results of frequent blood examinations were about as follows: Red cells 8,670,000, leucocytes 13,500, polynuclear neutrophiles 85. per cent., small lymphocytes 8 per cent., large lymphocytes 3 per cent., eosinophiles 2.5 per cent., hemoglobin 60 per cent.

I aspirated his chest for the first time October 15, 1904, and from that date until he died of the grip on May 19, 1906, 580 days, I aspirated his chest 311 times, averaging one aspiration every 1.9 days for the entire 19 months. The total amount of fluid withdrawn was 10,690 ounces or about 80 gallons, weighing nearly 700 lbs. The amount of fluid withdrawn at each aspiration varied from 12 to 110 ounces, averaging 34 ounces. There was an average daily loss through this channel of about 19½ ounces. As he averaged less than 16 ounces of urine each day, he passed more fluid through the aspirating needle than through the kidneys. The patient's average weight throughout his illness was about 140 lbs., and as I withdrew about 700 lbs. of fluid from his chest in 19 months, there was a loss through this channel of an amount equal to his bodily weight every 118 days.

The fluid withdrawn from his chest was usually a straw-colored serum, with a specific gravity of 1.030, containing 1.2 per cent. of albumin, epithelial cells, and a great deal of fibrin. Its coagulability was similar to that of normal blood. Occasionally the aspirating needle passed through a small vessel, and for some time afterward the serum would be more or less tinged with blood, and microscopically would show the presence of blood cells. This condition would gradually disappear and the serum return to its normal straw color.

During the first eight months the patient was aspirated on an average of once every five days; during the next two months, every other day. During the last six months of his illness he was aspirated 193 times, and there was withdrawn from his chest more than 5,600 ounces of serum—a daily average of over 31 ounces. Each side of his chest was aspirated on alternate days for most of this time, but during the last three weeks, on many days I aspirated his chest twice daily—that is, one side in the morning and the other side at night. During the last five days I aspirated each pleura twice daily. The day he died I was compelled to aspirate each side of his chest twice, and I also tapped his peritoneal cavity in an effort to relieve his terrible dyspnea.

The left side of his chest filled up more rapidly than the right and was tapped somewhat more frequently, and considerably more fluid was withdrawn from the left than from the right side. Of the last 200 tappings, 103 were on the left and 97 on the right side. The 103 left side tappings yielded about 3,100 ounces, an average of 30 ounces, and the 97 right side tappings yielded about 2,700 ounces, an average of almost 28 ounces for each tapping. Emptying the left side of his chest relieved his dyspnea more readily than when the right side was aspirated.

Early in his illness he was very tolerant of the effusion, and he would frequently go until a hundred ounces or more would be drawn from his chest, but later on in the disease his dyspnea would be extreme, and only thirty or forty ounces would be withdrawn, and toward the end he would suffer more dyspnea from a small quantity of fluid than he had formerly suffered when the large quantity was present.

These frequent operations were of necessity a great tax upon my time, but I found that by simplifying and systematizing the procedure I could sterilize the instruments, my hands, and the site of the puncture and complete the tapping in about twenty-five minutes, at the same time doing the operation aseptically. That it was done aseptically is proven by the fact that although the chest walls were punctured more than 400 times there never was the slightest evidence of infection in spite of the fact that I was operating frequently on all kinds of cases, clean and otherwise. I always made it a point, however, whenever I anticipated operating on a pus case, to tap this patient before the other operation. I endeavored to prepare my own hands, the site of the puncture and the instruments used in the operation with the same care necessary as for a laparotomy.

At first I used an ordinary aspirating needle with a beveled point, introducing it through the ninth, tenth, or eleventh costal interspace, at about the posterior axillary line. Owing to the pain and discomfort produced when the puncture was made too far anteriorly and the thickness of the chest walls when it was made too far posteriorly, I was limited to

about two inches of the eleventh, four inches of the tenth, and about three inches of the ninth interspace, and as the punctures were made so frequently it can be readily understood that a great deal of trouble was often encountered to find a place through which the needle had not recently penetrated. There was never the slightest evidence of infection at the side of the puncture, but the tissues became thick, brawny, and inelastic from frequent punctures, so that the needle in passing through would often carry with it a plug of tissue which would stop the flow of serum. When this occurred it was necessary to withdraw the needle and reintroduce it, and for this reason, although I aspirated his chest 311 times, it was sometimes necessary to make several punctures before the fluid would run freely. On one occasion I remember I was compelled to introduce the needle six times before I obtained a good stream. The frequent clogging of the needle and the constant danger of injuring the lung with the unprotected needle point led me to devise, with the aid of the patient, an aspirating needle better suited to the purpose and which we considered new. After having the needle made and using it for a couple of months we found that an almost identical needle had already been devised and manufactured in Germany. Our needle was an improvement on the German needle inasmuch as the shank of the trochar was much smaller than the caliber of the cannula, enabling us to see the flow of serum before the trochar was withdrawn. The employment of this needle minimized the danger of injuring the lung and the introduction of unsterilized air into the pleural cavities.

As an instance of how accustomed the human system may become to any condition, however abnormal, it may be stated that when this patient's chest was first aspirated at intervals of 10 or 12 days he suffered severely from shock and was 8 to 10 hours recovering from the operation, but later on when I was tapping him every day, removing at times as much fluid as I had formerly obtained, he had practically no shock and was able to go about as usual within a few minutes after the operation.

During his entire illness, and up to within a day or two of his death, the patient was able to go out, attend theaters, etc., and to a certain extent enjoy his existence. He did not lose as much weight as one might expect from the enormous loss of albumin through his kidneys and pleural effusion. This may be accounted for by the fact that from the first of his illness he had an abnormally large appetite, and appeared to suffer more acutely, both from dyspnea and abdominal pain whenever his stomach became empty and was only made comparatively comfortable when his stomach was full. Early in his illness it was his custom to eat heartily at least five times in 24 hours. He ate largely of eggs and other albuminoid foods. Later on he was compelled to eat oftener, especially at night. He partook of a fairly hearty meal every two or three hours. His stomach appeared to be able to assimilate this enormous quantity of food, for he seldom suffered from indigestion, although his condition prevented him from getting exercise.

As can be well imagined, the plans and methods of treatment employed in this very interesting case were very numerous and varied. In addition to what I did for him, the suggestions of a number of consultants, who very kindly saw him, were fully carried out. The patient, being a physician, spent about all his spare time reading up on his case, and many of his suggestions were tried. I doubt if he escaped a trial of any plan of treatment which did not carry with its employment too great a risk. In addition to the efforts of regular medicine, like a drowning man catching at a straw, he surreptitiously tried Christian Science, osteopathy, etc. After employing all the usual and unusual heart stimulants, diuretics, etc., we tried absolute bodily rest; the withdrawal of fluids; a non-saline diet; the intrapleural injection of adrenalin solution, etc., but I regret to say that everything had about the same result.

It seemed at first that the intrapleural injection of adrenalin diminished the secretion of serum, but the apparent improvement was only temporary and the serum returned in greater quantities than before. It also appeared that while the adrenalin caused a diminished secretion of serum in his pleuræ, the edema in his extremities was increased and there was no increase in the secretion of the urine.

Many plans for intrapleural injections of styptic and irritating substances to obliterate the pleural sacs were suggested, but the patient was afraid to allow them to be tried owing to the fact that both pleuræ were involved, and when adrenalin was injected the flow of serum lessened temporarily, but the amount of urine was not increased, and his extremities became more edematous. Permanent drainage was suggested, but the danger of infection seemed greater than the method we were employing, and the danger of collapsing his lungs was too great.

The patient was going along about as comfortably as he had been for many months, except that he was growing slightly weaker, and a smaller effusion in his chest produced such an amount of dyspnea as to make him uncomfortable, when early in May, 1905, he developed a well-marked attack of influenza, with a temperature rise to 103°. He at once began to suffer more acutely from dyspnea and abdominal distress, which were relieved only by removing the fluid from his chest more frequently than before. I was compelled at first to aspirate each side every day—one side in the morning and the other in the evening—removing from 18 to 20 ounces at each aspiration. The relief obtained was of very short duration and I was soon compelled to aspirate each side twice daily, withdrawing 12 to 15 ounces each time. He grew worse very rapidly, and during the last day of his life I was compelled to aspirate his chest four times and his abdomen once in the effort to relieve his distress. No autopsy was made.

The literature upon the subject of frequent aspirations for hydrothorax is particularly meager.

Pepper in his "System of Medicine" reports 22 aspirations at weekly intervals, where the total quantity of serum obtained was 1,563 ounces. At each tapping there was withdrawn from 49 to 112 ounces.

Ziemsen (*Deutsches Archiv. für klinische Medizin*, 1869. Vol. V) reports a case of double hydrothorax which he tapped 16 times, removing in all 420 ounces.

A. S. Joske of Australia (*Australasian Medical Journal*, 1887) reports a case which he aspirated 17 times at intervals of ten days, and when the case was discharged from the hospital there was fluid still remaining in the pleuræ. The subsequent history of the case is unknown.

In a quaint old volume on "Hydrothorax" written by MacLean in 1814 there is reported an old case of ovarian dropsy in a woman, whose tombstone in

a Scotch churchyard bears this interesting and unique epitaph:

Here lies Dame Mary Page,
Relict of Sir Gregory Page, Baronet.
She departed this life March 4, 1728,
In the 56 year of her age.
In 67 months she was tapped 66 times,
Had taken away 240 gallons of water
Without ever repining at her case
Or ever fearing the operation.

While the gross amount of fluid removed from Dame Mary Page's ovarian tumor exceeds the amount of fluid withdrawn from my patient's chest, she lost an average of 29 pints of fluid per month, while my patient's loss averaged 35 pints per month. During the last six months it averaged over 58 pints per month.

As far as I can ascertain from the medical literature at my disposal, this record of 311 aspirations of the pleural cavities, with the withdrawal of 10,690 ounces of serum in 19 months, stands as a record which has never been surpassed.

42 West Seventy-fifth Street.

ACUTE BULBAR PARALYSIS, WITH AN UNUSUAL SYMPTOM.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

ASSOCIATE IN NERVOUS AND MENTAL DISEASES, JEFFERSON MEDICAL COLLEGE; EXAMINER OF THE INSANE AT THE PHILADELPHIA HOSPITAL, ETC.

The case I am about to report presents an especially unusual feature, so that its classification is a matter of great difficulty.

Mrs. M. W., 40 years of age, housekeeper, in July, 1906, suddenly and without premonitory symptoms, became unconscious. She remained in a comatose state for three days. When she regained consciousness she was totally aphasic and her face was drawn to the right. Subsequently her speech improved, but never became normal. In December of the same year she had another attack, which was not accompanied by unconsciousness. It consisted of a sudden protrusion of the tongue and of a spasm of the jaws so that the tongue was caught between the teeth. The face became drawn to the left. For twenty-four hours the jaws could not be separated and the protruded portion of the tongue was swollen and injured from the insertion of the teeth. During this time the patient could not be fed. Gradually relaxation took place. The following symptoms were noticed: There was an inability to swallow, to move the tongue in any direction, to masticate; also difficulty of breathing, absolute loss of speech, and aphonia. The condition began to improve only at the end of a couple of months.

At present the patient presents the following symptoms: She can make sounds, but they are all monotonous and identical. She cannot utter a single word, syllable, or letter. Her face is deviated to the left. When she is told to show her teeth, the left nasolabial fold alone is deepened. When she is told to hold the lips tight together the face is drawn to the left. The tongue is thin, flabby, and affected with a fibrillary tremor; its movements are decidedly limited, and it presents the reaction of degeneration. The uvula is not elevated in attempts to swallow or to talk. The pharynx is anesthetic. There is still some difficulty in swallowing and in masticating. There is continuous salivation. She cannot bring the jaws tightly together. Blowing and whistling are almost impossible. The lower part of the face is wrinkled, and this, according to her sister, has been particularly marked lately. The lips are thin. The muscles of the right side of the face present partial reaction of degeneration. (CaClC=AnClC).

The grip of both hands is equal and normal. The gait is normal and there is no evidence of paralysis. The knee jerks are exaggerated and there is a paradoxical reflex on the right side, but no Babinski or Oppenheim. There are no sensory disturbances. Sphincters are normal. The eyes present no abnormality except a slight astigmatism. The epiglottis is in a state of a partial paralysis, allowing it to fall forward in inspiration. Aside from a slight engorgement of the arytenoids and of the cords, which approximate well, there is no other abnormality.

The intelligence is well preserved. She understands spoken or written words. There is no agraphia.

The heart is diseased. There is a systolic murmur at the apex. Her previous personal and family histories are negative. No evidence of specific infection could be detected.

Comment.—The difficulty of swallowing, of masticating, the limited movements of the tongue, and the atrophy of the latter are sufficient evidences in favor of a bulbar affection.

The diagnosis should be made chiefly between acute and chronic bulbar paralysis, also pseudobulbar palsy. In acute bulbar palsy the onset is sudden and accompanied by general symptoms, as headache, fever, and pain in the neck; the picture of glosso-labio-laryngeal palsy sets in rapidly. A comatose state appears and death is the usual termination. In my case, during the first attack, there was a sudden loss of consciousness, and the face became drawn to the right; the speech was totally lost. There was no involvement of the other cranial nerves. In the second attack, the twelfth, tenth, ninth, seventh, and motor part of the fifth became involved, but there was no loss of consciousness. Besides, a total loss of speech is not a symptom of acute bulbar palsy. In chronic bulbar paralysis the onset is insidious. There is at first a dysarthria and later anarthria, but total mutism is not characteristic of this affection. Besides, the lips being immobile the mouth remains open. The facies appears stupid. In my case the onset, the mutism, and the expression of the face militate against the chronic form of bulbar palsy.

With psuedobulbar palsy my case presents this similarity, that there were two apoplectiform seizures, but on the other hand, there was no hemiplegia. In pseudobulbar palsy there is a difficulty of swallowing, of masticating, and of speaking (dysarthria) but what especially characterizes this affection is absence of atrophy and fibrillary tremors in the paralyzed muscles, preservation of normal electrical reactions, and, finally, mental disturbances, such as loss of memory, apathy, confusion, and dementia. Attacks of laughing or crying are almost typical of the pseudobulbar palsy. My case is, therefore, not an example of the latter disease.

Summing up the history and the symptoms of the case, one can see that while it presents some of the manifestations of each of these three affections, it is nevertheless wanting in some of the typical symptoms. Is it a case of amyotrophic lateral sclerosis with an irregular bulbar onset? The

*Read and patient exhibited before the Philadelphia Neurological Society, November 26, 1907.

state of the knee-jerks with the presence of the paradoxical reflex seem to favor this view.

Irrespective of the view we may adopt, there is one symptom which it is difficult to explain, viz., the loss of speech. All the affections of the medulla usually give place to a dysarthria or anarthria. A complete inability to speak can be present only when the atrophy and the degenerative reactions are very much pronounced in the muscles participating in enunciation of words. In my case the condition of the lips, tongue, palate, and larynx is not such as to abolish entirely their function.

In aphemia of cerebral origin there is loss of ability to articulate words, but the patient is always able to emit sounds or syllables which resemble more or less words. My patient is completely deprived of the power of pronouncing even letters.

Is it finally a case of hysteria? The persistent difficulty of swallowing, of masticating, the atrophy, fibrillary contraction and reaction of degeneration of the tongue, atrophy and reaction of degeneration of the muscles of the face, are certainly against the conception of hysteria. Moreover, the patient presents no stigmata of this neurosis.

1130 Pine Street.

SIGNIFICANT FEATURES OF MIDDLE-EAR SUPPURATIONS IN INFANCY AND CHILDHOOD.*

By S. J. KOPETZKY, M.D.,

NEW YORK.

ATTENDING OTOLOGIST, N. Y. CHILDREN'S HOSPITALS AND SCHOOLS, ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL, PATHOLOGIST NEW YORK NOSE, THROAT, AND LUNG HOSPITAL.

The study of the distinctive features of ear disease, as it affects the infant and young child, is of especial importance no less for the otologist than for the pediatrist. The fact that a considerable number of all cases of ear disease occurs in children is both significant and suggestive. Accounted for to a certain extent by the susceptibility of the young to the common infectious diseases, such as scarlet fever, diphtheria, and measles, the prevalence of ear affections in children is largely referable to the local anatomical characteristics of the immature auditory apparatus. These are reinforced by the greater vulnerability of the youthful nervous system, the tendency to convulsions, and the relatively slight resistance of the growing organism against the effect of general intoxication through the entrance of toxalbumins into the circulation. Hence, the pathological conditions of the organs of special sense, more particularly the ear, in the child are characterized by certain distinctive features, indicative of the reaction of the juvenile organism to the invasion of the injurious agent.

The very evident predisposition of the growing ear to infections both primary and secondary, rests upon the anatomical basis of structural peculiarities, for the auditory apparatus of the newborn child is far from having reached full maturity. It is a common observation that an organ at rest is less liable to disease than one which is undergoing either progressive or retrogressive changes. The slight resistance of the immature petrous bone is still further diminished by the delicate structure of the juvenile skeleton as a whole, and by the histological behavior of the tympanic mucosa, with its greater vascularity and more abundant secretion in the young. The tympanic cavity at this early age contains many remains of embryonic tissue, which upon the entrance of bacterial invasion of only slight virulence is easily broken down, with the result that suppuration becomes established. In certain cases, this suppuration persists during a more or less prolonged period, without any external signs to indicate the gravity of the underlying lesion.

The Eustachian tube in the infant and young child is short, almost straight, and its wide open lumen affords an outlet for the accumulating pus. This spares the drum, and explains the peculiarly significant feature of the ear suppuration among these patients, namely the preservation of an imperforate drum, with or without bulging, until late in the course of the disease. The discharge of the Eustachian tube brings in its train a series of symptoms which are significant. These are gastrointestinal disturbances, the functional derangement being associated with a considerable loss of body weight. I recently had under observation a child who, because of diarrhea and loss of weight, accompanied by vomiting, was put for some time upon a diet of various modified milks. No suspicion was attached to the ears, until there suddenly appeared facial paralysis, closely followed by otorrhea. It must be borne in mind that the bowels may be involved coincidentally with the ear disease, prior to it, or in consequence of it. In such cases, the attempt to analyze the clinical picture, to differentiate the general from the local disease, is beset with additional difficulties.

In certain cases in my experience the nutrition of the child was impaired, and there was an unmistakable departure from the normal standard. Meanwhile, the attending physician had been unable to locate the disturbing factor, and our own otoscopic examination demonstrated only a thickened drum. These cases remained obscure until an examination of the pharynx showed a purulent exudate coming from the Eustachian tube. The patients were a girl of three, and two boys of three and two years of age, respectively; in the case of the youngest patient, the purulent exudate also came away from the nostril of the affected side.

With special reference to intestinal disturbances, these have actually been reported by many observers as coincident with ear disease, and to these cases may be added a personal observation. Whereas some have held the bowel derangement and vomiting responsible for the ear trouble (Goppert[1]), others interpret the bowel derangement as the result of the ear trouble (Preysing, Ponfik, Hartman); and Jacobi believes both contentions to be founded on fact. Preysing, whose conclusions seem the most trustworthy,[2] regards the diarrhea as a kind of septic diarrhea, and recalls to mind the fact that the pneumococcus—the most frequently offending microorganism—belongs to that class of streptococci which are causal agents of sepsis; it having been demonstrated that streptococcus toxins cause diarrhea (Homer and Laetinen[3]).

Whatever may be the cause of the gastrointestinal disturbance, it remains a fact that one often sees the onset and the termination of the disease in the ear, synchronous with the onset and termination of the bowel derangement, and I hold with Gomperz that any one who has observed this must be impressed with the direct effect produced upon the entire body by ear suppuration in infancy, the bowel derangement being a manifestation of this systemic effect.

*Read at the Eastern Medical Society, New York City, January 10, 1907.

The presence of the colon bacillus was pointed out in the middle ear by Stern,[4] and in octogenetic brain abscess by Lentert. According to Baginsky, this bacterium plays a rather important part in the middle-ear affections of children.

Kossel[5] demonstrated the Löffler diphtheria bacillus in acute otitis media of children having diphtheria. Primary otitis media diphtheria was observed by Krepuska, Kobrak, and Hans Daae.[6]

Experience teaches that a number of other pathogenic microorganisms play a part in the production of inflammatory middle-ear disease. According to the investigations of Zaufal and others, the diplococcus pneumoniæ enters into consideration in the etiology of primary acute otitis media. The streptococcus, the *Staphylococcus pyogenes albus* and *aureus,* and Friedlander's pneumonia bacillus, may be involved in the remaining secondary infections. The clinical variations observed in a number of cases have been demonstrated as due to the invasion of different bacteria. It is claimed, for instance, that acute otitis media due to pneumococcus infection takes a more rapid course, and is more liable to be complicated by epidural abscess, the result of propagation of the inflammation to adjacent organs (Leutert).

The etiology of otitis media in infants is identical with the etiology of the disease in adult patients. In either group of cases, a number of pathogenic microorganisms have been demonstrated, which had reached the tympanic cavity either through the Eustachian tube, or by the hematogenous route (Kossel, Preysing, loc. cit.).

A brief glance may be given to the otitis media of the newborn, an independent disorder which has of recent years been referred to the presence of a foreign body, by the investigations of Aschoff.[7] He showed that the mucopurulent secretion frequently met with in the tympanic cavities of newborn children, contains a considerable admixture of amniotic fluid, vernix caseosa, and meconium. While these substances do give rise to cellular infiltration of the mucosa, the changes are never as severe as those usually observed in the infectious forms of otitis. These cases constitute mild attacks of otitis, with an inflammatory transudate, rather than a physiological process due to the absorption of fetal tissues.

Whereas, in adults, middle-ear suppurations only occasionally produce a rise of temperature, in infants and young children the febrile movement is more or less the rule. This is present even when the disease is limited to the tympanic cavity. When the mastoid antrum becomes the seat of an empyema, then the temperature usually rises sharply, and convulsions among the younger patients are by no means rare. After the disease has spread to the mastoid antrum (there is no mastoid process in the infant) the destruction of osseous tissue is rapid indeed. We are often surprised in the operative findings of these cases, at the amount of destruction, which seems out of all proportion to the evident symptoms. Bearing in mind this frequent finding, in connection with the ever-recurrent presence of defects in the osseous encasement of the facial nerve, we can in a measure account for the early paralysis of the facial nerve, another significant feature of middle-ear suppuration at this age. Reflexes from the ear are much more commonly observed in children than in adults.

While not intending to dicuss the anatomy of the infant's and child's temporal bone, I cannot refrain from calling attention to the frequency with which the dome of the jugular bulb is in direct contact with the lining mucosa of the middle ear. These defects in the floor of the tympanum are quite frequent, and they probably account for the great susceptibility of these small children to otitic pyemia. I have seen cases in which the opening of the mastoid antrum was followed by symptoms which were interpreted as evidence of sinus-thrombosis, and the sinus was explored, only to be found normal. In such cases had the possibility of septic pyemia due to absorption of toxins from the wall of the sinus at the bulb through the defect in the floor of the middle ear been borne in mind, the character of the case under consideration would have been self-evident.

Children are peculiarly susceptible to the so-called meningitic or pseudomeningitic type of middle-ear disease, and the explanation has been sought in the direct transmission to the brain of inflammatory stimuli through the open petrosquamous fissure of the immature petrous bone, resulting in cerebral hyperemia, with meningitic symptoms. Again, increased air-pressure through compression of the stapes has been held responsible (otopiesis). The most probable explanation seems to be the absorption of pus and toxalbumins in the circulation, the severity of individual cases being dependent upon the character of the pus in the tympanic cavity, the amount of pathogenic bacteria contained in it, the vicinity of the brain and the conditions governing the degree of absorption. (Baginsky.[8])

Brief mention should be made in this connection of a rare but extremely dangerous type of meningitic ear disease—true primary inflammation of the labyrinth, or otitis intima. These cases are practically limited to children, and often leave behind them a total bilateral deafness, the exact etiology of which has been the subject of animated controversy.

The differentiation between otitic pyemia and the involvement of the bulb or the sinus calls for the highest exercise of diagnostic skill. Red marrow bone (the type of bone in the developing mastoid of the young) is liable to rapid destruction, often laying the lateral and the sigmoid sinus open to attack. Anatomically, the open sutures, the petrosquamous, the squamomastoid, etc., furnish routes of infection to the cranium more readily than they do under similar conditions in the adult. It is, therefore, of importance that the middle-ear condition and the empyema of the mastoid antrum be promptly recognized and surgically relieved, so as to anticipate intracranial complications. Through the open sutures pus may easily work its way to the outside, and the appearance of a subperiosteal abscess is significant of this condition in childhood. The abscess in these cases is as a rule located above and not behind the ear. Furthermore, periosteal abscesses develop rather easily in childhood, because of the exceeding thinness of the external wall of the antrum, and these patients usually present well-marked symptoms of increased brain-pressure (diffuse or unilateral headache, somnolence, vomiting, retardation of pulse, optic neuritis). However, as in the case of an eight-year-old girl operated upon by Lane,[9] there may be a large accumulation of pus between the dura and the bone, without giving rise to symptoms.

Whereas empyemas of the mastoid process in early life very often give few if any distinctive symptoms, and are easily overlooked, the acute empyemas of the mastoid antrum characteristically, though not invariably, present a rather profuse

otorrhea, with a light sanguineous tinge. The discharge is demonstrably coming away under pressure. Occasionally the soft canal wall is separated from its bony parts by the extravasation of pus, and in one case seen by the writer, the drum remaining intact, the drum and soft canal became everted like the turned-in end of a glove finger, this presenting at the external auditory meatus, like a new growth. Free incision, removal of pus and replacement of the everted part of the canal were followed by recovery.

Swelling of the gland at the angle of the jaw, with a particularly fetid otorrhea, is sometimes the only symptom pointing to mastoid involvement in children having constitutional stigmata, or suffering from malnutrition and marasmus.

The external auditory canal usually narrows because of inflammatory swelling of its walls, presenting superficial ulceration from excoriation by the pus. I place more weight on this narrowing of the canal than on the sinking of the posterior superior quadrant, as the former in my experience is the more reliable guide in childhood.

Facial paralysis, coming on early in the disease, while it may presage grave involvement of the mastoid, is not a reliable sign, for the exposed nerve is somewhat open to attack by way of the not uncommon defects in its bony casing. Again, children are especially susceptible to reflexes from the ear.

Brain abscess presents nothing characteristic in childhood, except that apparently uncomplicated cases often show distinct meningitic symptoms. Basillar meningitis may develop through invasion of the cranial cavity by way of perforation of the tegmen tympani through the labyrinth and porus acusticus internus, or in very young children through the various open sutures, the subarcuate hiatus, or a dehiscent facial nerve canal. Koerner pointed out the noteworthy fact that all those intracranial complications of ear suppuration which may be interpreted as a toxic meningoencephalitis, preferably concern youthful individuals. Among twenty patients, eleven were under fifteen years of age.

In conclusion we find the significant features of middle-ear suppuration in infancy and childhood to lie (1) in the existence of the purulency without perforation; (2) in the presence of a discharge from the Eustachian tube to the pharnyx; (3) in the exhibition of temperature, early facial paralysis and marked disturbance of stomach and bowel; (4) in the advent of periosteal abscess; (5) in the rapid progress of destructive processes in the petrous bone; (6) in the tendency to intracranial complications; (7) in the possibility of early primary bulbar thrombosis; (8) in the existence without thrombosis of otitic pyemia, and (9) in the relatively serious sequelæ of certain forms of ear disease in the child, who is exposed to the danger of deaf-mutism by the loss of a special sense so intimately related to the function of speech.

DANGERS ATTENDING OPERATIVE INTERVENTION IN GONORRHEAL SALPINGITIS.*

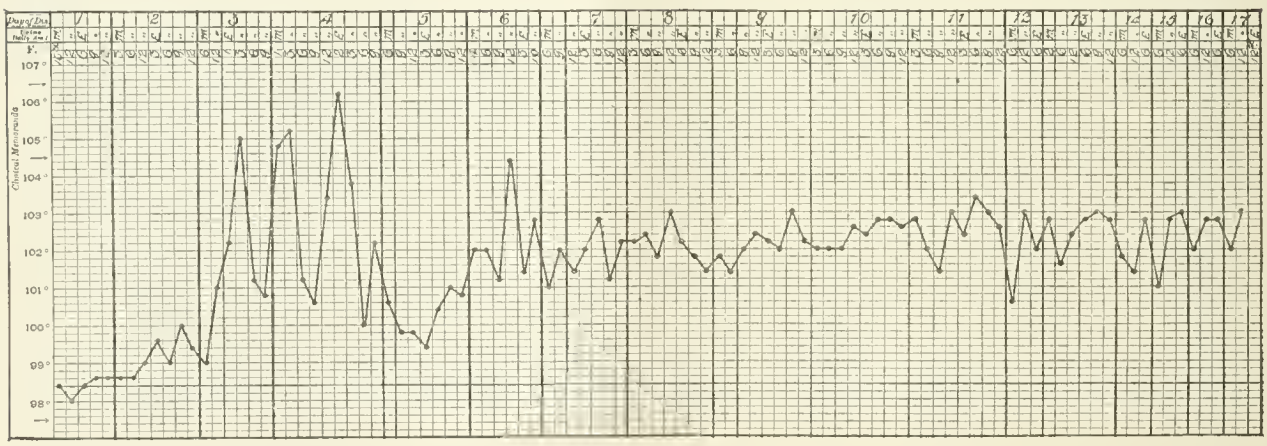
REPORT OF A CASE.

By J. S. PRICE, M.D.,

BEAUMONT, TEXAS.

Mrs. A. of Port Arthur was referred to me for operation, after about two months of suffering, following a gonnorrheal infection from her husband, to which he confessed.

Upon examination, the uterus was found fixed,



the tubes and ovaries could be easily palpated, and gave evidence of having been badly damaged by the inflammatory process, which the normal temperature led me to believe was in abeyance. She continued to suffer, however, from pelvic distress, for the relief of which she constantly clamored for morphine.

Operation was performed on November 7, 1906, and both tubes, along with one ovary, were removed. Adhesions plastering the uterus to the surrounding intestines were liberated and the abdomen was closed. The patient was returned to bed in good shape, and, of course, we expected the usual, normal convalescence. But herein lies our story.

On the afternoon of the second day there was a slight elevation of temperature, followed in the after-

*Read before the Section on Obstetrics and Gynecology of the Southeast Texas Medical Association.

noon of the third day by a distinct chill, temperature reaching 105°, which readily yielded to cold sponge bath. On the fourth day, another chill, temperature 106.4°. Fever on the fifth day, 101° at its highest. The afternoon temperature of the sixth day was 104.4°, with distinct swelling of the joints, which, up to this time, had given no evidence of disturbance. This showed that we had an explanation, outside of the belly cavity, for the high temperature.

The stitches were removed on the eighth day, the wound having healed without the slightest trouble, and at no time were there any symptoms, beyond the fever, pointing to trouble in the operative field.

As will be noted on the clinical chart, the patient died on the fifteenth day of the disease without any warning. Only a few minutes prior to her death she called for the nurse to turn her in a more comfortable position. Death was, most likely, due to gonorrheal endocarditis.

The purpose of this report is to call attention to the likelihood of gonorrheal rheumatism being awakened by operation in specific infections where active symptoms are in abeyance, and to the fact that this systemic infection may eventuate fatally.

ETHER ANESTHESIA.

By DEAN LOREE, M.D.,

ANN ARBOR, MICH.

FIRST ASSISTANT IN SURGERY, AND LECTURER IN GENITOURINARY SURGERY, UNIVERSITY OF MICHIGAN

In the past the mere selection of ether over chloroform has been deemed sufficient precaution without attempting a study of the possibilities of the latter. The profession seems to be awakening to the fact that proper etherization calls for experience and that, within certain limits, a maximum dosage must be established.

Much is being written concerning the different forms of apparatus and this or that method calls for much or little commendation, whereas the true test is the anesthetist himself and that mode of administration is superior which in his hands permits him to employ the smallest quantities of ether. Mechanical improvements make men idlers. Before giving the anesthetist the results of too much inventive genius he must first be taught that it is but a means to an end, else it enables him the more easily to slip into the old rut made deep and smooth by past years of disregard. Every agent for real good has an equal power for evil if not properly employed, and this is true of appliances for administration of ether. Carbon dioxide poisoning resulting from the use of certain closed inhalers as seen many times in some hospitals, is pernicious.

The drop method has done more for ether in general than any one thing since its discovery. I have never used it myself, but make the statement because of the small amounts necessary for surgical procedures reported in recent papers. Averages of five ounces of ether per hour may be obtained with the Allis inhaler slightly modified. I do not use one from choice, but prefer some form of closed inhaler as in my hands it conserves the drug. This statement may, perhaps, not be borne out by those who have become proficient with the drop method and open administration. Nitrous oxide gas preceding ether is unnecessary; the former is valuable in selected cases, not only for minor but, if properly given, may be prolonged for major operations. Primary anesthesia with ether is valuable in many short operations, viz., extraction of teeth, incision of abscesses, urethral dilatations, etc. It is possible to make fourteen extractions with primary anesthesia lasting ten minutes, counting from the time the inhaler is adjusted until the patient is talking intelligently or is able to clear the mouth of blood.

The average amount of ether required per hour is four ounces. I am not now speaking of those operations confined in part to insensitive tissues, but when complete unconsciousness must be continuous. The longer the operation is prolonged the less ether is necessary for any given period of time. The longest period of ether anesthesia that has come under my observation was five and one-half hours, in the case of a radical mastoid operation with exploration of the brain and ligation of the left common carotid; the amount of ether used was fourteen ounces.

Some surgeons, following the example of the Mayos, are looking for their ideals in this branch outside the profession, as compared with the surgical technique which necessitates its use it seems to have little attracion for some medical men, while others disregard its importance and deem it too narrow a field for special work.

Proficiency in the future will require the minimum amount of ether instead of the promiscuous "soaking" of the past. When this is made obligatory, vomiting is the exception, not the rule; the excitement stage is wanting; the intense irritation of bronchial mucous membrane is never experienced, and the capillary circulation is as good, sometimes better, than before administration.

In the following list of anesthesias the cases have been taken in their order, with the exception of the operations within the peritoneal cavity, when the drug may be discontinued for many minutes during certain periods.

Case I.—Radical breast amputation. Ether. Time, forty-three minutes. Amount of ether, two and one-half ounces.

Case II.—Amputation of cervix. Ether. Time, forty-five minutes. Amount, three ounces.

Case III.—Resection of upper jaw preceded by tracheotomy. After the tracheal tube was inserted ether was given by a common rubber funnel covered with gauze and inserted into the tube. Time, two hours. Amount, eleven ounces and six drams.

Case IV.—Mastoid. Ether. Time, two hours and fifty-five minutes. Amount, ten ounces.

Case V.—Thigh amputation. Nitrous oxide gas. Time, nineteen minutes.

Case VI.—Cystotomy. Nitrous oxide gas. Time, fifteen minutes.

Case VII.—Cancer of rectum. Ether. Time, forty-eight minutes. Amount, three and one-half ounces.

Case VIII.—Circumcision and varicocele. Ether. Time, twenty-six minutes. Amount, two ounces.

Case IX.—Secondary carcinoma in cervical glands of the neck and deep cervical fascia. Ether. Time, three hours and twenty-five minutes. Amount, ten ounces.

Case X.—Inguinal hernia. Time, one hour. Amount of ether, three and one-half ounces.

Case XI.—Thyroidectomy. Time, one hour and five minutes. Amount of ether, three ounces and six drams.

Tests for acetone have been positive in some cases, but as it appeared principally in those patients who have had the shortest periods of narcosis and necessarily the smallest amounts of ether, little importance is attached as yet to its appearance. Complications, either immediate or remote, will rarely be encountered under this low dosage. He who is skillful in the giving of ether will have little time to wander outside his own field of usefulness.

MEDICAL RECORD.

New York, February 29, 1908.

THE OPERATIVE TREATMENT OF PUERPERAL THROMBOPHLEBITIS.

THE idea of curing thrombophlebitis by proximal ligation or resection of the inflamed vein came of a practical investigation not so very long ago. In 1865 Lee tied off the cephalic vein, and in 1877 Kraussold the femoral vein, and soon afterward the ear specialists, first among them Zaufal, in 1884, ligated or resected the internal jugular vein for thrombosis. The ear specialists met with such marked success, partly because the anatomical relations of the parts were such that the seat of the thrombosis could be easily gotten at and partly because they had no trouble in deciding whether the trouble was on the right or left side. Encouraged by their good results, Sippel, Freund, Bumm, and Trendelenburg tried the same treatment in thrombophlebitis of the pelvic veins. They, however, did not obtain equally favorable results, because they had greater difficulty in deciding which side was involved and in telling before operation how far the thrombus extended, for if the renal, inferior vena cava, or common iliac vein is involved success is impossible.

The number of reported cases of operation for puerperal phlebitis is still very small. L. Seitz (*Volkmann's klinische Vorträge*, No. 464, series XVI) has recently collected thirty-seven, giving a detailed description of each case. He draws attention to the frequency of puerperal thrombophlebitis, it being found in one-half of the cases of puerperal sepsis which come to autopsy. It is important to note that the placental site is the usual portal of infection, and that the process is rarely combined with an inflammation propagated along the lymphatics. If the portal of infection were situated lower down in the genital tract the large collateral circulation would make the operation useless, and if any inflammation along the lymphatics were also present the latter would be uninfluenced by the operation. As regards the most frequent location of the disease, opinions differ. Bumm and Trendelenburg believe it to be in the internal iliac, the latter having found it there in fourteen out of twenty cases; he also found the condition to be bilateral in two-thirds of the cases. Lenhartz, on the other hand, in thirty-two autopsies found the internal iliac involved only five times, the ovarian having been involved in the other cases; in only one-fifth of his cases was the phlebitis present on both sides. Seegert found the ovarian involved in all out of twenty-five autopsies; in nineteen the condition was unilateral. It is, therefore, safe to state that the ovarian vein is more frequently affected than the internal iliac.

The prognosis in unoperated cases has been variously reported; as a rule, large figures show a better prognosis than small ones. Thus Bumm's mortality among twenty-three cases was 83 per cent.; Lenhartz among eighty-seven cases, all severe forms of the disease, noted a mortality of 69 per cent., while Opits collected 339 cases, with a mortality of but 60.5 per cent. On an average 66 2-3 per cent. of the severe cases treated conservatively terminate fatally. Of the thirty-seven operated cases collected by Seitz, all of which were severe forms of thrombophlebitis, fourteen terminated in recovery, *i.e.* the mortality was 62 per cent. Of the twenty-three patients who died an autopsy was performed on nineteen. Ten showed a vena cava thrombosis, which in itself is usually fatal; one died of cardiac disease which was present before operation; three had a septic pneumonia with an abscess of the lung before operation; one died of peritonitis present at operation, and in three the vein was not ligated proximally to the thrombus, *i.e.* only part of the thrombus was excluded from the circulation. One died of a retroperitoneal abscess which developed after operation, so that this was the only case in which death could be attributed to the operation; the others would have ended fatally even if they had not been operated upon. When the diagnosis is made it is hard to decide in which cases operation is indicated and when to operate.

The indications for operation are not always definite. As a general rule, all severe forms are operable cases. Seitz thinks it unwise to be guided by the number of chills, as suggested by Trendelenburg, who believed operation indicated after two chills. Seitz admits that a sharp distinction cannot be made between acute and chronic cases, but for practical purposes classifies those which last longer than two weeks as chronic, advising operation in the chronic stage. The mortality among twelve patients operated upon in the acute stage was 75 per cent.; among twenty-four operated on in the chronic stage, 54 per cent. He, however, warns against waiting too long, for then the vena cava may have become implicated and the operation thus rendered useless; autopsies show that the cava rarely becomes involved before the end of the third week. Septic pneumonia, abscess of the lung, septic endocarditis, metastases in the kidney, and pelvic cellulitis he considers contraindications. He advises median laparotomy as the operation of choice, for the vaginal route gives poor exposure, while the extraperitoneal operation exposes only one side; the first mentioned has given the best results. He advises resection only in those cases in which the inflamed vein looks as if it might rupture; in the remainder he operates according to Bumm, *i.e.* ligates the internal iliac and ovarian veins on both sides, unless he is positive that the disease is confined to one side. Even then he ligates both the internal iliac and the ovarian veins, although only one of them may seem to be involved.

The usual objection advanced against tthe operative treatment of puerperal thrombophlebitis is not that the operation is dangerous, but that we have no proof that the operation was the cause of cure when

the patient recovered. Would not the patient also have gotten well if no operation had been performed? is the usual question asked by the opponents of this method of treatment. Of course, it is hard to prove positively that the patient would not have gotten well, but as seven out of the fourteen patients who were operated upon and recovered had no further chills after operation, when they had them daily before operation, it seems only just to attribute their recovery to this mode of treatment. And when the patients had only one or two chills after operation and then recovered, we could certainly not speak of an unsuccessful treatment, but would probably be right in claiming that the operation brought about the final cure. These last-mentioned cases can be explained on the ground that all the infectious material has not been excluded from the circulation and that a collateral circulation sets in at once, thrombi in small veins not being necessarily excluded, even though both internal iliac and ovarian veins are ligated. The body then takes care of the remaining amounts of infectious material, the number of chills after operation depending on the quantitative reduction of the infectious material excluded from the circulation. Those fatal cases in which chills are absent for a few days after operation and then reappear are explained on the ground that the collateral circulation sets in only after a few days and that the body is not able to take care of the remaining infectious material. The operative treatment of this condition, therefore, not only seems justifiable in selected cases at the proper time, but promises to reduce the mortality in severe forms of puerperal pelvic thrombophlebitis.

TRICHINIASIS.

Trichiniasis is a disease with which the general practitioner of medicine is not very familiar. Often enough the phenomena of infection with this nematode are quite obscure and the cases are classed as "atypical" typhoid fever or as influenza. The given patient, of course, suffers but little from such mistakes in diagnosis; we have no specific treatment for this infection, and it runs its usual course, characterized by gastroenteric symptoms of varying severity, fever, indefinite muscular pains and tenderness, and edema of the face, especially marked about the eyelids. The patient usually recovers, though he carries with him after the disease the encysted embryos of the parasite that sooner or later undergo calcification. In some epidemics many cases have shown a more serious grade of infection, the mortality ranging from 2 to 30 per cent. But, while there is no specific treatment for the disease, we fortunately possess abundant knowledge of its prophylaxis, which should consist in the first place of careful and systematic examination of all swine flesh at the slaughter houses, and in thorough cooking of all meat in all cases where the possibility of infection has not been previously excluded. It is in this connection that the correct recognition of cases is of value, so that the importance of the prophylactic measures may be realized by the public and by the sanitary authorities before further harm is done.

In No. 3, Vol. VII, of *Russkii Vratch*, Dr. K. H. Georgievsky gives an interesting account of an endemic of the disease in Kharkof, Russia. For several years cases showing the above symptom-complex were observed, but their true nature was not recognized. Finally, in the year 1907, a number of such cases occurred in the practice of Dr. Georgievsky, whose suspicions were aroused. A careful examination of the blood showed marked eosinophilia, no reason for which could be found, though the stools were thoroughly searched for parasites. The diagnosis of trichiniasis was made and was soon confirmed by the examination of bits of muscle taken from the patients. Dr. Georgievsky presented the matter before the medical society of the city, and doubts were expressed about the identity of this epidemic with the milder cases noted on previous occasions. Fortunately a physician who had been attacked some time before consented to an examination, and in his muscles were found the encysted embryos of the nematode, thus proving the contention of the author.

This story is of interest, for it shows that while the general practitioner cannot be expected to perform the various technical procedures demanded in the study of disease in the hospitals, yet a careful examination of the blood is called for in all obscure cases. The eosinophilia associated with trichiniasis was first studied by American workers, and no doubt its significance will henceforth be as well appreciated by the Russian physicians, after their experience in this Kharkof endemic.

THE OPHTHALMO-REACTION IN TUBERCULOSIS.

In June, 1907, Calmette published a method of diagnosing tuberculosis which depends upon the reaction of the conjunctiva to tuberculin. As is now well known, one drop of a one per cent. solution of tuberculin instilled into the inner canthus of a healthy individual's eye causes no change in the eye, while it excites an inflammatory reaction of varying intensity in persons afflicted with tuberculosis. Calmette differentiates between a mild reaction, redness of the inner canthus and lacrymal caruncle; a moderate reaction, redness which involves the bulbous conjunctiva just beyond the caruncle; and an intense reaction, redness which involves the whole conjunctiva. Other observers have reported a large series of cases in which the test was tried. All agree that the test is harmless and that a positive reaction is a sure sign of tuberculosis. Later reports, however, do not justify this favorable opinion.

In the *Correspondenz-Blatt für Schweizer Aerzte* for January 15, 1908, Stoll reports his results in twenty-five individuals with absolutely healthy eyes. In seven, in whom a positive clinical diagnosis of tuberculosis was made, the reaction was positive in all, though only to a mild degree in the advanced cases. In five, clinically suspicious of tuberculosis, the reaction was positive three times and negative twice. In the remaining thirteen individuals, in whom tuberculosis was excluded clinically, nine positive and four negative reactions were observed. Stoll thus obtained a positive reaction in all the cases diagnosed clinically as tuberculosis and in two-thirds of

the cases in which no physical signs of tuberculosis were found. Other observers not only reported a large number of positive reactions in persons apparently free from tuberculosis (in a few instances substantiated by autopsy), but also negative results in tuberculous patients. Outside of a severe conjunctivitis in one patient, which lasted two weeks, Stoll saw no ill effects from the instillations, but others have reported cases of iritis, keratitis, and corneal ulcers caused by the tuberculin applications.

If these results are confirmed by others, one will be forced to conclude that the reaction is of little value as an aid to the diagnosis of tuberculosis and that it is not so harmless as was once considered. When positive in tuberculous patients, the intensity of the reaction is no criterion for the degree of tuberculosis.

A Notable Defense of Vivisection.

The members of the Woman's Auxiliary of the Society for the Prevention of Cruelty to Animals were treated to a surprise last week as they listened to an eloquent defense of vivisection by their president, Mrs. Cadwalader Jones. The speaker said that she had received many letters requesting her to declare her views on the vivisection question, and she therefore did so, but probably not in the way expected by many of her correspondents. Mrs. Jones said that she was a lover of animals, especially of dogs, and she admitted, as do most physiologists and experimenters, that vivisection might be abused and that animals undoubtedly had been tortured needlessly in the name of science, yet she held that vivisection was necessary and that great good had come to mankind through its practice. As an illustration of one of the many benefits it had conferred upon humanity she instanced the discovery of diphtheria antitoxin, which has greatly lessened suffering and saved the lives of innumerable children. Any one, she said, who, twenty years ago, saw children choking to death from diphtheria and now sees the results of antitoxin treatment cannot but bless this discovery which was made by experiments on animals. She defended the workers in the Rockefeller Institute, which has been made a special object of attack by the advocates of more stringent antivivisection laws, and exposed the falsity of the assertion that there was now no restriction on the practice of vivisection in this State. The present law provides that animal experiments shall be performed only under the authority of the faculty of some regularly incorporated medical college or university in the State of New York. This is an all-sufficient guarantee that animals will not be submitted to aimless experimentation or one that is not conducted in furtherance of scientific ends. Mrs. Jones quoted this law, and said that violators of it, or any who inflicted needless cruelty on animals, could be brought to justice; but she contended that the benefits to humanity of vivisection were very real and justified its practice. The opposition to vivisection comes from well-meaning but uninstructed persons whose hearts are larger than their heads, and who have never taken the trouble to examine the question from any but the sentimental side; they will not listen to arguments on the other side, for they come from what they regard as prejudicial sources. Such an able defense of vivisection by a woman whose life is devoted to the protection of animals from cruelty at the hands of man must appeal to the fair-minded opponents of this necessary practice and cannot but work for good to the cause of suffering humanity.

Intussusception.

The slipping of one portion of the intestine into an adjacent portion has been generally attributed to abnormal or excessive contraction of the muscular coat of the bowel, especially in the face of distal resistance or obstruction. It is most common in infancy and childhood and it is favored by a number of anatomical conditions, for example, undue length of the mesentery and the presence of a valve-like formation at the junction of the large and small intestine. While admitting the significance of the foregoing factors, Dr. John D. Rushmore (*Annals of Surgery*, August, 1907) contends that the contents of the bowel must play an important part in the immediate causation of the disorder, the starting point of which he maintains may consist in the presence of substances that by their bulk or chemical characters excite spasm or irregular contraction of the muscular layer. As the result of an analysis of 301 cases collected from various sources, and including two of his own, Dr. Rushmore defines intussusception as a form of internal strangulated hernia, the symptoms of which, except the tumor, are in almost all cases evident and striking, even to the layman, the diagnosis being comparatively easy to the medical observer. When a tumor is not readily palpable, a general anesthetic should be employed for diagnostic purposes rather than wait for the development of a tumor palpable subsequently. Any other than surgical treatment cannot be depended upon, and this should be instituted not only within the first twenty-four hours, but within the first twelve hours, as only in this way can the more grave dangers of gangrene be averted. Celiotomy and manual reduction offer the best chance of recovery. Mechanical means of reduction short of direct manipulation, such as air, gas, water, oil, etc., while free from the danger of atmospheric exposure and contamination by the hands, are objectionable because they fail to reveal the condition of the intestine to be reduced. While the mortality from operation on young infants for intussusception has been relatively high, early operative interference may be expected to yield a low mortality—at present about 12.5 per cent.

News of the Week.

Army Medical Corps Examinations.—Preliminary examinations for appointment of assistant surgeons in the army will be held on May 4 and August 3, 1908, at points to be hereafter designated. Full information can be procured upon application to the Surgeon-General, United States Army, Washington, D. C. The essential requirements are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to the localities from which applications are received in order to lessen the traveling expenses of applicants as much as possible. In order to perfect all necessary arrangements for the examina-

tions of May 4, applications must be complete and in possession of the Surgeon-General on or before April 1. There are at present twenty-three vacancies in the medical corps of the army.

Lectures at the New York Skin and Cancer Hospital.—The governors of the New York Skin and Cancer Hospital, Second avenue, corner Nineteenth street, announce that the following lectures will be given in the Out-Patient Hall of the hospital on Wednesday afternoons, at 4:15 o'clock: Dr. L. Duncan Bulkley, "Pathology in Its Practical Bearings Upon the Treatment of Certain Diseases of the Skin," March 4; also clinical lectures on Diseases of the Skin, until April 15. Dr. William Seaman Bainbridge, on the Treatment of Unremovable Cancer, with exhibition of cases, April 22, 1908. The lectures will be free to the medical profession.

Fire in Brooklyn Hospital.—The main buildings of the Norwegian Hospital, at Fourth avenue and Forty-sixth street, Brooklyn, were endangered last Saturday by a fire which broke out in a two-story frame outbuilding about thirty feet in the rear of the hospital proper and used as a storehouse for supplies. The fire was held in check by the hospital staff and citizens until the arrival of the firemen, when it was extinguished before it had spread to the other parts of the hospital.

Premature Burial.—A bill now under consideration in the Massachusetts Legislature provides that in every case of apparent death of a human being eleven specified tests for the discovery of life shall be applied to the body before preparations for burial are begun. The tests would be made by two physicians in person, one of them representing the Board of Health, and the cost of the service would be borne by the town or city in which the death occurred. None of the tests provided for in the bill is of such a nature as to arouse the opposition of surviving kinsmen or friends, but their number suggests the thought that perhaps, after all, none of them is very reliable.

Instruction in Medical Schools Regarding the U. S. Pharmacopœia.—At an informal conference recently called by Prof. Joseph P. Remington, and attended by sixteen prominent teachers in the medical schools of Philadelphia, the following resolution was passed: *Resolved*, That it is of the utmost importance for accuracy in prescribing, and in the treatment of disease, that students of medicine be instructed fully as to those portions of the United States Pharmacopœia which are of value to the practitioner, and that members of the medical profession be urged to prescribe the preparations of that publication; and further, that this resolution be forwarded to the medical and pharmaceutical journals and to the teachers of medicine and therapeutics in the United States.

Tea Adulteration.—Tea importers are in favor of a movement urging Congress to pass a law transferring the tea inspection service from the Treasury Department to the Agricultural Department in order to stop the use of coloring matter in the cheaper grades of tea and to secure better enforcement of the regulations against adulterants. It is alleged that many of the cheaper grades of teas which come here are colored with indigo and talc to make them look like the better grades, and that this coloring matter is deleterious to the health.

Monthly Bulletin of the Medical Society of the County of Kings.—Beginning with the current year, this society is issuing every month, except July and August, an excellent eight-page bulletin, designed to keep the members advised of all matters pertaining to the society's work, its various activities, its membership, and other subjects of general interest. In order to make the bulletin as useful as possible, each member is urged to become a frequent contributor of news items to its columns.

Institute of Experimental Medicine in Brazil.—The Brazilian Government has voted funds for the establishment of an experimental pathological institute at Manguinhos, intended for the study of the parasitic and infectious diseases of man, animals and plants, and for the preparation of serums.—*Science.*

Institution for the Teaching of the History of Medicine.—The project of founding in Vienna an institution for instruction in the history of medicine seems assured of success, as the government has promised a subvention and liberal contributions have been received from members of the profession. A building is shortly to be erected to serve as a museum, containing collections of objects relating to the development of medicine, such as instruments, portraits, books, etc. Professors Neuburger and von Töply have been the leaders in the enterprise.

Snakes in India.—The British Government has decided to distribute as widely as possible among the natives of India the special lancets for the treatment of snake-bite devised by Sir Lauder Brunton. These are so arranged that the handle contains a quantity of permanganate of potassium which is to be rubbed into the bite after this has been freely incised by means of the knife blade.

Tuberculosis in Sweden.—The Swedish Commission for the Prevention of Tuberculosis in a recent report to the government recommends the establishment by degrees of 4,600 sanatoria, at a total expense of nearly eleven million crowns. These institutions are to be supported by the municipalities.

A New Use of a Poison.—Several cases of death in the poorer quarters of the city have occurred lately as the result of poisoning with nitrobenzol. Some of these apparently were suicides, but it is suggested that the habitués of the resorts in this part of the city have become familiar with the toxic properties of the agent and are using it as a form of knockout drops.

Gift to the Berlin Library.—Professor Hirschberg, the prominent Berlin ophthalmologist, has informed the directors of the Berlin Royal Library that in his will he presents his collection of works on ophthalmology to the library, together with an endowment of $4,000, the income of which is to be used for subscriptions to periodicals on the same subject.

Honors for Lord Lister.—Under ceremonies of considerable pomp Lord Lister was on January 21 made an honorary burgess of the city of Glasgow. It was while professor of surgery in the University of Glasgow that Lord Lister made the researches that have given him his imperishable place in the annals of medicine.

Dr. William Seaman Bainbridge of this city has recently been appointed consulting surgeon to the Manhattan State Hospital.

Municipal Hospital of Philadelphia.—The following appointments have been announced: Dr. J. Earl Ash, first assistant resident physician, at $900 a year; Dr. Edward T. Clement, second assistant resident physician, at $800 a year; Dr. John T. Adylote, third assistant resident physician, at

$800 a year; Dr. J. Roy McKnight, first assistant resident, on the nonsalaried staff; Dr. Charles J. Swalm, second resident physician, on the nonsalaried staff.

Philadelphia Hospital.—Dr. Henry D. Jump has been appointed registrar, Dr. Herman Schwatt outdoor physician, and Dr. Charles S. Potts a member of the advisory board of the department for the insane.

Tulane University.—Work is soon to be begun on the new Richardson Memorial Building of Tulane University, New Orleans. The building is to cost about $200,000, and will have three stories and a basement, which will be devoted to laboratories, research rooms, and administration offices. It is expected to be ready by next October.

Nassau Hospital.—The new wing of the Nassau (L. I.) Hospital was opened on February 22 in the presence of Dr. Cleveland, Dr. Holbrook Curtis, Dr. William P. Bull, and numerous benefactors of the institution.

Mumps at Bryn Mawr.—An epidemic of mumps has appeared at Bryn Mawr, ten or fifteen cases having been reported and a considerable number of students are in quarantine

No Cholera at Acapulco.—The officials of the Mexican Superior Board of Health deny the allegations transmitted to the United States Navy Department that cholera is epidemic in Acapulco and affirm that no cases of the disease have occurred. The smaller vessels of Admiral Evans' fleet are due to arrive at Acapulso late in March.

New York Orthopedic Hospital.—The concert for the benefit of the New York Orthopedic Hospital held at the Waldorf-Astoria last week was largely attended and a satisfactory sum was realized for the hospital.

Street Railway Accidents During January.—A report of the accidents happening on the railroads of the city for the month of January made to the Public Service Commission shows that there was a slight falling off as compared with those reported for December. The total for that month was 3,993, and for January, 3,921. Fifty-one persons were killed in December and 44 in January.

Dermatologische Zeitschrift.—This periodical, which was formerly under the direction of the late Prof. O. Lassar, will in future be issued in enlarged form, under the editorship of Drs. A. Blaschko of Berlin, K. Herxheimer of Frankfurt, E. Huffmann of Berlin, V. Klingmüller of Kiel, and M. Wolters of Rostock. The publication office will be: Professor E. Hoffmann, Berlin, N. W., Schiffbauerdamm, 29.

Freemont County (Wyo.) Medical Association.—An organization with this name was formed at a meeting held at Lander and the following officers elected: *President,* Dr. Thomas G. Maghee, of Lander; *Vice-President,* Dr. N. D. Nelson of Shoshoni.

Terrebonne Parish (La.) Medical Society.—The following officers were elected at the reorganization of this society effected at a meeting held in Houma on February 9: *President,* Dr. J. B. Duval; *Vice-Presidents,* Dr. A. J. Delcourt and Dr. R. M. Calmore; *Treasurer,* Dr. L. J. Menville; *Secretary,* Dr. A. P. Delcourt.

Eastern Hampden (Mass.) Medical Association.—The following officers were elected for this society at the meeting held on February 13: *President,* Dr. H. G. Stetson of Greenfield; *Vice-President,* Dr. H. C. Martin; *Secretary and Treasurer,* Dr. M. B. Hodgkins of Monson.

Manila Medical Society.—At the meeting of this society held on January 8 the following officers were elected for the ensuing year: *President,* Dr. Harry T. Marshall; *Vice-President,* Dr. James M. Phalen; *Secretary-Treasurer,* Dr. Philip Garrison; *Councillor,* Dr. H. D. Kneedler.

Iowa Clinical Surgical Society.—The second annual meeting of this society was held in Des Moines on February 6 and the following officers were elected: *President,* Dr. Wilton McCarthy; *Vice-President,* Dr. Donald McCray; *Secretary and Treasurer,* Dr. D. S. Fairchild.

Death of Professor Voit.—On January 31 Geheimrat Carl von Volt of Munich died, at the age of seventy-eight years, after a short illness from miliary tuberculosis. Professor Voit, who was one of the pioneers in the investigation of the problems of metabolism, was for forty-five years a member of the faculty of the University of Munich.

In Memory of the Late Rabbi Gustav Gottheil a ward with an endowment of $10,000 is to be established in the Beth Israel Hospital.

Obituary Notes.—Dr. Wm. Badger of Flushing, L. I., died on February 13, at the age of seventy-four years. He was born in Andover, Mass., and after attending Phillips Andover was graduated from the College of Physicians and Surgeons in this city and held several hospital appointments. In 1862 he was made superintendent of the United States Army Hospital on David's Island, New York Harbor, and later he organized a State hospital for soldiers at Manchester, N. H. He retired from practice six years ago.

Dr. Leo Dansiger of Cincinnati was shot and instantly killed on February 14 by a demented patient. He was a native of Cincinnati and had practised in that city since his graduation from the medical department of the University of Cincinnati, in 1892.

Dr. L. H. Laidley of St. Louis died suddenly on February 5 of apoplexy, at the age of sixty-four years. He was born in Carmichael, Pa., and had come to St. Louis in 1872. He was professor of gynecology in St. Louis University and chief surgeon of the St. Louis Protestant Hospital. He was medical director of the recent World's Fair.

Dr. Andros P. Chesley of Concord, N. H., died on February 9 of nephritis. He was born in Epsom, N. H., in 1855 and was graduated from Dartmouth College in 1880. Three years later he received his medical degree from Long Island College Hospital.

Dr. P. W. Pope of Nevada, Mo., died of heart disease on February 3, at the age of fifty-six years. He was born in Jamesville, Wis., and was a graduate of the Keokuk Medical College. He had practised in Nevada for about fifteen years.

Dr. Allen F. Hammond of Montello, Mass., died January 27, at the age of thirty-seven years. He was born in Mattapoisett and was graduated from the medical department of Boston University in 1893.

Dr. Charles H. Morse of Marquette, Mich., died on February 3 of paralysis, in his seventy-first year. Dr. Morse was born in Nova Scotia and was graduated from Harvard in the class of 1868. He had practised in Marquette for about sixteen years. He leaves a son, Dr. W. H. Morse of Marquette.

Dr. Orlando Mixter of Worcester, Mass., died on February 6, at the age of sixty-six years, after a long illness. He was born in Leicester and received his medical education in the New York University Medical School. He had practised in Worcester for many years.

Dr. William L. Stovall of Bellefontaine, Miss., died on January 31, at the age of eighty-five years. He had practised in Bellefontaine for forty-seven years.

Dr. Henry C. Wood died at West Chester, Pa., on February 12. He was gradnated from the Hahnemann Medical College of Philadelphia in the class of 1867. He served as a surgeon in the United States Army during the Civil War.

Dr. William M. Urquhart of Orange, N. J., died of pneumonia on February 20, at the age of thirty-four years. He was born at Bradford, Pa., and was graduated from the University of Pennsylvania Medical School. During the Spanish-American War he served as assistant surgeon in the Sixteenth Pennsylvania Regiment.

Dr. Oscar Burbank of Waverley, Iowa, died on February 7, at the age of eighty-eight years. He was born in Massachusetts and was graduated from Harvard University in 1848. He had practised in Waverley for fifty-four years.

Dr. A. P. Chesney of Concord, N. H., died of nephritis on February 9, at the age of fifty-three years. He was born in Epsom and was graduated from Dartmouth College in 1880, receiving his medical degree three years later from Long Island College Hospital. He had practised in Concord for almost twenty-five years.

Dr. J. M. Jones of Newport, Ark., died of pneumonia on February 13, at the age of sixty-two years. He had practised in Newport for more than thirty years.

Dr. B. S. Crawford of Keokuk, Iowa, died on February 13 at the home of his son, Dr. B. S. Crawford of St. Joseph, Mo. Dr. Crawford was born in Illinois sixty-three years ago and was graduated from Keokuk Medical College.

Dr. Henry C. Morrison of Kansas City died on February 7, at the age of sixty-five years. He was born near Baltimore, Md., and served through the Civil War as assistant surgeon in the Twenty-sixth Pennsylvania Regiment. He had practised in Kansas City since 1870.

Dr. Lawrence E. Holmes of Asheville, N. C., died on February 8, at the age of thirty-five years. Dr. Holmes was born in England and was graduated from the University of Pennsylvania Medical School in 1897. Since 1901 he had been a resident of Asheville.

Dr. George Alfred Baxter of Chattanooga, Tenn., died on February 12, at the age of fifty-seven years. He was born near Asheville, N. C., and was graduated from Hobart College in 1871, receiving his medical degree from Bellevue Hospital Medical School. He began practice in Chattanooga in 1873 and was one of the first to perform ovariotomy in the State. He had held many positions as railway surgeon and distinguished himself during the yellow fever epidemic of 1878.

Dr. George A. Robinson of Sayville, L. I., died at St. Augustine, Fla., on February 22, at the age of fifty-seven years. He was a native of Newmarket, Canada, and had practised in Sayville for nearly thirty years.

Longevity in Turkey.—It is asserted that no other country produces so many instances of extraordinary longevity as Turkey, many such cases having been satisfactorily proven. There is said to be at present living in Keni Baghtcha a government bookbinder aged 134 years, who has held his position for eighty years. His father was also a government functionary, and died at the age of 142 years.

Correspondence.

CHLORINE AS A GERMICIDE.

To the Editor of the Medical Record:

Sir:—My repeated and continuous success in the use of chlorine for now close on twenty years has convinced me that others will find it invaluable and obtain similar excellent results. In acute tonsillitis without pus its astringency relieves quickly the congestion. In quinsy it is of great service as a gargle or spray or both—it seems to combine with and "eat away" the pus very rapidly and leave a red surface which soon subsides.

In diphtheria before the days of antitoxin I used it exclusively as a gargle and spray combined in attacking the membrane. If swallowed at all it does not nauseate or inconvenience—in fact my old chief, Dr. Lyon, gave it internally as well in doses of two teaspoonfuls every hour to children. As an adjuvant to antitoxin it is excellent. In inflamed states of the gums, abscesses from caries of teeth, etc., he used it freely as a mouth wash.

Seeing such good results on the throat I have applied it to the treatment of infected wounds of all kinds for nearly two years, and in fact have discarded everything else for it—whitlows, abscesses, local or diffused cellulitis with multiple incisions, foul ulcers—in fact any conditions where pus exists—sometimes by continual immersion in the solution or by packing wounds with sterilized dressings dipped in the solution.

In some books it is stated that chlorine lotion produces irritation of the skin surrounding a wound—personally I have never once found it do so.

Below I give a formula for the making of this chlorine solution; it is the original formula of Dr. Lyon, of County Durham, England.

Formula.—Take stoppered bottle to hold one quart. Warm it gently; place 80 grains of powder of potassium chlorate in the bottle, then add 80 minims of strong hydrochloric acid and close tight. Wait three or four minutes, till all the powder has dissolved and the free chlorine gas has been evolved. Then remove the stopper and quickly add one-half pint of cold water and shake vigorously so that as quickly as possible a solution is made of the chlorine gas. Then add water till the quart is made up. Allow it to stand for an hour before using.

A fresh solution is to be made each day. This is important. If the solution feels too strong on gargling dilute with an equal amount of cold water.

INSTRUCTION TO SUFFERERS FROM VENEREAL DISEASE.

To the Editor of the Medical Record:

Sir:—Early last fall I published papers dealing with instructions to those having syphilis, chancroids, and gonorrhea, respectively in the Medical Record, *New York Medical Journal*, and the *Long Island Medical Journal*. As this matter of printed instructions is very rarely dealt with in the medical press, and in fact is usually totally neglected, I gave very little attention to the detail of looking up literature. All the more because I aimed not to publish anything new, but rather to state successful clinical experience in this rather accurate way of dealing with the venereal patient of our clinics.

My friend Dr. Follen Cabot has written me that about nine years ago he published circulars on the same subject, excepting chancroid, and also that about a year ago he read a brief paper before the American Society of Moral and Sanitary Prophylaxis on the same point. These papers escaped my attention largely because the titles thereof are rather long and involved and thus were passed by, in the matter of looking up data on "instructions." I desire by this letter to give Dr. Cabot full credit and to agree with him in the fact that one receives very little encouragement in these matters.

For example, at first many of my colleagues at the New York Hospital and House of Relief doubted the wisdom of such circulars, but experience has shown them to be both wise and serviceable.

I ventured to write to the Surgeons-General of the United States Army and United States Navy, due to an inquiry from one of the surgeons in the Marine Hospital Service about these circulars. The Army replied most courteously and sent me a pamphlet of their own much like what I have written. The Navy, on the other hand, has not even acknowledged my letter.

I likewise wrote to the local Board of Health asking whether instructions might not be issued by the board in

these diseases similar to those published for tuberculosis. The question appealed to me as somewhat public-spirited and perhaps commendable, but up to the present writing no acknowledgment of the letter has been given. The fact remains, however, that in our experience these instructions are most advantageous, which concurs with the experience of men like Fournier in Paris and Cabot in this city. It is hoped that others may find it worth while to try the question out themselves. V. C. PEDERSEN, M.D.

AMPUTATION OF THE FOREARM *IN UTERO*.

To the Editor of the Medical Record:

Sir:—The following case is, I think, of sufficient interest to be worthy of a report. About 4 o'clock in the afternoon of December 31, 1907, Mrs. J., a multipara about thirty-five years of age, was delivered of a still-born male child. On the morning of January 1, 1908, the writer was called to deliver the placenta. Labor, according to both the patient and midwife, had been long and tedious, lasting over thirty-six hours before the birth of the child.

The child's left hand was found to be entirely wanting, the left forearm being amputated about midway between the elbow and wrist. In every other respect, with the exception of a cyanotic appearance, the child seemed perfectly normal, and from this and the history of the case it seems probable that death was due to pressure upon the cord during the birth. The amputation had healed perfectly by a linear scar which extended from before backward across the end of the stump and thence vertically for about one inch on the dorsal surface of the forearm, just as if it had been done by a circular and an intersecting vertical incision on the dorsal aspect of the forearm. The skin on the end of the stump was loose and slightly puckered. Upon being questioned the midwife stated that at the birth of the child the left arm was in a vertical position, the stump of the forearm resting against the back of the neck. The cord passed over the neck from right to left and was resting against the end of the stump, the amputation being brought about in all probability by prolonged pressure by the cord. The vertical scar on the back of the forearm was due to the oblique direction in which the cord crossed. The placenta was found lying in the vagina. The patient had bled profusely, but nothing unusual was noticed in her discharge, either during or following labor. Her recovery was uneventful. IVAN P. BATTLE, M.D.

ROCKY MOUNT, N. C.

EDUCATION OF THE BLIND-DEAF.

To the Editor of the Medical Record:

Sir:—May a layman ask the medical profession to do great good? The prevailing notion is that the education of the blind-deaf is "wonderful," very abstruse, requiring special fitness, etc. A very large majority of the blind-deaf come from ignorant parents, who do not know that the education of such children is entirely within the scope of any school for the deaf.

Now, if physicians generally would tell parents of such children that the deaf school of their State can educate these children there would not be so many neglected ones, buried in darkness.

To be certain in the statement I make, that any school for the deaf *can* educate a blind-deaf child, not feeble-minded also, all the physician has to do is to write to the superintendent of the deaf school in his State.

WILLIAM WADE.

OAKMONT, PA.

MEDICAL EVIDENCE IN CRIMINAL CASES WHERE THE PLEA OF DEFENCE IS INSANITY.

To the Editor of the Medical Record:

Sir:—The alienist, as a rule, is called only when the nature of the condition has been recognized by the family or friends. The general practitioner observes his patients, their histories, their strength and weakness, physical and mental, as no specialist can possibly. He watches the evolution of their maladies and traces them to their origin. Therefore in mental disturbances of any kind his opinion is much more likely to be correct than that of the specialist.

It is difficult to get a correct history in mental affections. The family generally deny any hereditary taint, and thus deceive the physician if possible; but the observant doctor knows that when one parent is phthisical and the other neurotic, the offspring may be and often is insane. Then again when there is a syphilitic taint, one may have violent attacks of insanity, lasting from a few minutes to twenty-four hours, and then become perfectly clear mentally. In such cases the evidence of the general practitioner is more likely to be correct than that of the alienist. It is a mistake to suppose that the intellect or reasoning faculty is solely disordered in persons afflicted with mental derangement. There are many cases to be met with in which it consists in a morbid perversion of the moral affections, without any perceptible lesion of the intellectual faculties.

There are madmen in whom it is difficult to discover any trace of hallucination, but there are none in whom the passions and moral affections are not perverted or destroyed. The most productive causes of the complaint are love, fear, reverse of fortune, domestic chagrin, or family dissensions. Physical causes are much more commonly the origin of insanity than is generally supposed. The observant physician sees the premonitions of insanity in many families, but is cautious about calling their attention to it for obvious reasons. Insanity is supposed to cast a stigma upon any family in which it may make its appearance; consequently the members of such family are most desirous of concealing the existence of any such condition until it unfortunately develops itself. The origin of the evil is to be sought for in that artificial state of society which grows necessarily out of constant advancement and civilization. We multiply our comforts and in consequence our cares and crosses, we beat out and expand our minds as it were and thus create a more extended surface for impression.

J. H. O'DONNELL, M.D.

WINNIPEG, MANITOBA.

THE MENTAL STATE PRECEDING A HOMICIDE.

To the Editor of the Medical Record:

Sir:—The opportunity of studying the mental condition of a murderer about one hour previous to the commission of the crime is so rare that a report of such a case may be of interest to students of criminology.

Having been employed by a district attorney to examine a man under indictment and awaiting trial for manslaughter, and in whose defense a plea of insanity was about to be made, it became necessary for me to visit him in the county jail. I made the journey by electric railroad. The car was well filled, with one empty seat by my side. After riding a short distance we came to a stop and J. boarded the car. J. at that time was about twenty-five years old, the son of respectable parents, natives of Ireland, and of good family history. He had recently received an honorable discharge from the regular army. As I had treated him before his enlistment for a fractured metacarpal bone, he recognized me and, without hesitation, took the empty seat by my side. He presented every evidence of having been upon a prolonged debauch: his breath was strong with the intensely offensive odor of stale whiskey, his face was badly bruised, and, while he did not noticeably stagger, there was some muscular incoordination. Myosis was pronounced, and, as nearly as I could determine by careful observation, his pupils were rigid and sluggish of reflex. His mental condition, however, at once attracted my attention. His ego was excessively exalted. He seemed to be full of delusions as to his mental and physical excellence, his delusions somewhat resembling those of a paretic dement. Coupled with these delusions was an intense combativeness, which, I learned subsequently, was a prominent trait of a waywardness of character manifested from early youth. In conversation he stated that he had always worsted a prominent local attorney in the trial of cases; that he had been blown up by a charge of dynamite higher than the walls of a deep rock cut, through which we were passing, and had alighted unhurt. As a proof of his physical prowess he proposed to throw the conductor into Bloody pond when we arrived there. A man boarded the car out in the country. J. proposed that I should get into a dispute with him when he would take my part and "do the countryman."

Having reached my destination, I left the car. J. rode six miles to the next village, entered a hotel and very shortly became involved in a fight with a colored man. The proprietor came to the aid of J.'s antagonist and the two, after beating him, threw him out of doors. J. then unlocked his trunk, which stood on the porch of the hotel, took out a loaded revolver, and, entering the hotel again, shot the landlord, inflicting a mortal wound. He was indicted for murder in the first degree, tried, and found guilty of murder in the second degree, and is now serving a life sentence. No question of mental irresponsibility was raised by his counsel.

I saw him a few weeks later, while confined and awaiting trial. He was then in good mental condition, and, after

having served five years of his sentence, he still remains so. While the verdict in his case was doubtless just and necessary to safeguard the rights of society, it is doubtful if J. at the time of the homicide could be called a person of sane mind.

Did he understand the nature and quality of his act, and, if so, could he refrain from its commission?

OUR LONDON LETTER.

(From Our Special Correspondent.

LETTSOMIAN LECTURE—TUBERCULOUS ENDOCARDITIS—KINEMATOGRAPH AND X-RAYS IN DIAGNOSIS—THYMIC ASTHMA—CHEMICAL ANTISEPTICS IN OPERATIONS—LEES-RAPER LECTURE—OBITUARY.

LONDON, February [illegible], 1908.

TUBERCULOSIS of the kidney was the subject of a Lettsomian lecture at the Medical Society of London on Monday by Mr. Charters Symonds of Guy's Hospital. He devoted it mainly to the early signs and the effects of operations, pointing out the necessity of examining the urine in cases of renal colic, especially in young patients, as well as the great significance of vesical and urethral irritation; also percentage over amount of albumin in the urine greater than would result from the presence of pus. These points were illustrated by interesting cases. In one a young lady of twenty had an attack of renal colic. Two years later a second and a few months after that a third. Albumin had been noticed three months, with a little pus. *X*-rays gave a negative result. Bacilli were looked for and found. The cystoscope showed tuberculosis around the right ureter and swelling of the orifice. The right kidney was therefore removed and showed long-standing tuberculous mischief, with some fresh miliary tubercles. Under tuberculin treatment she recovered.

Another illustration was a man of 46, out of health for two years, during which time he suffered from renal colic on two occasions. It was thought that a calculus had passed into the bladder, but none was found. Then the urine was examined for bacilli, which were present. On cystoscopic examination there was prolapse with edema of the right ureteric orifice. The kidney was removed and showed old cicatrices and contraction of lower pole, with recent miliary tubercle in the cortex and pelvis. The bladder symptoms disappeared after the operation.

Vesical irritation may be the only symptom, as in the case of a young woman who was troubled with it for a year. The cystoscope showed a healthy bladder, but the lips of the right ureteric orifice were swollen and marked by a number of white elevations. The right kidney was removed. Its lower half was extensively diseased and fresh clumps of tubercle tissue occupied the cortex and pelvis. The ureter was removed also. Rapid recovery ensued.

A lady of 40 had attacks of abdominal discomfort, scarcely pain, mostly at night, for a couple of years. Then vesical irritation set in. A large amount of albumin with only a little pus in the urine was suggestive of tubercle, and bacilli being looked for were found. The bladder also was tuberculous, ulceration was present near the right ureteric orifice, the margins of which were, however, normal, and the urine flowing was clear. Tuberculin treatment was tried, but without benefit, for ten months, when rigors set in, the temperature rose, a painful renal tumor formed, and much pus was discharged. Nephrectomy was done, the ureter being left. There were cavities in the kidney full of pus, obliteration of much of the pelvis with one ulcerated channel leading from some of the cavities to the ureter, suggesting a recent communication between these after disease of long standing.

A lady of 30, suddenly seized with rigors and hyperpyrexia and signs of septicemia, was found to have been troubled for months with vesical irritation. On exploration the left kidney was found enlarged and was incised through the loin with evacuation of pus and subsidence of symptoms. Later on the kidney was removed and found tuberculous. The bladder symptoms still continued and the whole ureter was removed. After this recovery occurred and the patient is now quite well—ten years after the operation.

Tuberculous endocarditis was the subject of a paper at the Royal Society of Medicine by Dr. W. O. Meek. He related two cases of miliary tuberculosis with vegetative endocarditis due to the tubercle bacillus. The condition is rare so far as the literature shows. In one case there were rigors, pyrexia, etc., during life and at the necropsy [illegible] of small recent vegetations on the mitral and aortic valves were found, also recent infarcts in the spleen and liver. Under the microscope the vegetation appeared as a granular necrotic material with a zone of [illegible] cellular proliferation at the junction with the valve. Throughout the vegetation there were large numbers of tubercle bacilli, in parts forming [illegible] and in their deeper parts were circular foci of caseation in which bacilli were included. No giant cells. In the infarcted areas clumps of bacilli occupied the blocked vessels. Cultures from the spleen were sterile after four days. No other microbes. In the other case there was advanced miliary tuberculosis. In this there [illegible] vegetations on the mitral valve, histologically similar to those of the first case. Bacilli were scattered through the lesion sparingly. No other microbes. That the bacilli were the cause of the vegetation, the author admitted was doubtful in this, though he considered they certainly were in the other case.

In the Medical Section on the 28th ult. Dr. Campbell Thomson showed kinematographs of abnormal attitudes and gaits and the display elicited remarks on the value of this method in analyzing complex movements in disease of the nervous system. Dr. Hertz also read a paper describing investigations by *x*-rays and meals containing bismuth to show the passage of the food through the alimentary canal, chiefly with a view of elucidating the problems of chronic constipation. A diffuse shadow was seen as a meal passed through the small intestine, but it was scarcely to be traced in the larger bowel on account, perhaps, of the dilution with the fluids in the greater area.

In the Clinical Section a case of sudden dyspepsia in a boy of 5½, which terminated fatally in three and a half days, was related by Dr. Sidney Phillips. There was 110° fever and nothing detectable in larynx, lungs, heart, or urine, and no sign of mediastinal pressure. At the post mortem there was found some enlargement of the thymus and mesenteric glands and spleen. It was suggested that the case was one of those formerly called thymic asthma. There seemed to be no laryngeal spasm and laryngismus does not take such a course as this or kill off in such a way. Pultauf considers that enlarged thymus or other gland sets up a constitutional state in which there is a tendency to cardiac failure. Escherich and Blumler seem to entertain somewhat similar views. In some cases resembling this relief has been obtained by raising the enlarged thymus from the trachea, and Dr. Sutherland mentioned that he had seen this done. The practice would seem natural, considering that Morfans found the trachea flattened by the enlarged thymus and Dr. Poynton had seen a case in which there was dullness due to the enlarged thymus. Some have held that these cases are due to "status lymphaticus," a term which Dr. Bernstein said was too often a cloak for ignorance. Dr. A. Russell remarked that in health the thymus ranged from 5 to 10 drams in weight, but in cases such as these it was generally 25 drams.

Mr. Lockwood read a paper at the Medical Society of London on the 27th ult. urging that the use of chemicals for banishing bacteria from the field of operation should not be given up. Wound infection, he said, came from the hands and person of the surgeon and his assistants, from the skin of the patient, and from the atmosphere. He himself uses the spirit and biniodide lotion. This is really a solution of mercuric iodide in potassium iodide. Alcohol is a powerful germicide and has the advantage of removing cutaneous grease. Mr. Lockwood's practice is after washing his hands to soak them for not less than two minutes in spirit and biniodide lotion and transfer them repeatedly from that to a watery solution of biniodide (1 in 2,000). The biniodide does not combine chemically with the skin, but some of it remains closely connected with it. Care and accuracy are required and therefore inexperienced assistants should wear gloves. Considering that asepsis depends on saturating the skin, Mr Lockwood has the patients' skin treated in the same way for at least three minutes. Atmospheric infection or environment infection, as it might be called, might be due to coughing and other sources. He had had no ill results from the use of chemical antiseptic solutions in his operations.

The eighth Lees-Raper lecture was delivered at Oxford on Tuesday by Mr McAdam Eccles under the presidency of Professor Osler. The relation of alcohol to national efficiency was trenchantly treated by the lecturer. He said the action of alcohol on living tissue tended to the deterioration of the individual and of the race. It was specially potent in child life. The effect on infants, whether taken through the mother's milk or from spoon or glass, was so bad that many hospitals issued warnings con-

cerning it. Alcohol began to act on the child before its birth, continued its evil effect in infancy and was too often perpetuated afterwards. National deterioration led to loss of supremacy and active measures were required to stem the tide flowing over the land. Mr. Eccles suggested a number of such measures which our legislators might consider, closing with the suggestion that to alter the trend of public opinion the universities should encourage research into the problems involved and publish the results with the weight of their authority. This, he thought, would help the politicians and social reformers.

Mr. William Allingham died on Tuesday, aged 78, at Worthing, to which he had for some time retired. He was for many years surgeon to St. Mark's Hospital for Fistula and to the Great Northern Hospital. He took his M.R.C.S. in 1855 and two years later the Fellowship by examination. He had been demonstrator of anatomy and surgical registrar at his hospital (St. Thomas's.) His work on "Diseases of the Rectum" went through several editions. He was a contributor of various cases to the journals and societies and long enjoyed an extensive practice, particularly in surgical diseases of the lower bowel.

(From Our Special Correspondent.)

OPENING OF NEW BUILDING FOR MEDICAL DEPARTMENT AT QUEENS UNIVERSITY—HOSPITAL REORGANIZATION AT TORONTO—LEGISLATION FOR MEDICAL INSPECTION OF SCHOOLS.

TORONTO, January 25, 1908.

THE new medical college at Queens University, Kingston, was opened with appropriate ceremonies on Tuesday last. The new building, which is handsome in design and well constructed, has been carefully planned to provide, in addition to well-appointed lecture halls, a complete series of medical laboratories, equipped with all the requisites for practical work. The formal opening was marked with great success. The chair was occupied by Principal Gordon and with him on the platform were representatives from all the leading Canadian universities. The opening address was delivered by Dr. L. E. Barker of Baltimore, a Canadian graduate, who always receives a cordial welcome in this country. Dr. Barker's theme was "Medical Laboratories," a subject which he treated in all its phases. Reference was made at length to many important discoveries which research work had brought to light, and the necessity of having properly equipped laboratories in connection with every medical college was now generally recognized. To the students, Dr. Barker pointed out, laboratory facilities opened a field from which a harvest of hidden truths might with industry be gleaned. Hon. Dr. Pyne, Minister of Education for Ontario; Dean Reeve and Professor MacCallum of Toronto University; Professor Adami and Professor Mills of McGill University, Montreal, were the other speakers. Each one referred in congratulatory terms to the excellent work Queens University was doing for the cause of medical education in Canada, and expressed themselves delighted with the new and modernly equipped building in which Professors and students were to find such greatly improved facilities for carrying on their work.

The trustees of Toronto General Hospital have for some time had under consideration a scheme for the reorganization of the staff in connection with that institution. The requirements by Toronto University of adequate facilities for clinical instruction have been carefully considered in discussing and adopting the plans decided upon. In making appointments to the visiting staff previous training and record, capacity to render service to the sick in the hospital, scientific attainments, teaching ability, and the promise afforded for future work have alone governed the trustees. The members of the staff, who are without salary and have to be reappointed annually, are not to be allowed to serve on the staff of any other hospital. The following services have been instituted: In medicine (including dermatology and neurology) three coordinate services, in surgery three coordinate services, in obstetrics one service, in gynecology one service, in ophthalmology one service, in otology, rhinology, and laryngology one service. With respect to the coordinate services in medicine and surgery it is understood that the decision reached by the committee at the present time and with regard to the existing situation is not to preclude the trustees at any future time from reopening the question and considering whether a different system might not better serve the interests of the hospital and of medical education in connection therewith. Each of the services in the several departments shall be under a head, with such associates and assistants as may be found necessary. The several services in all departments shall be so organized as to include both indoor and outdoor patients, and the heads of such services shall be responsible for the treatment of all such patients. The heads in surgery must retire from their position at the age of 55 and the heads in medicine at the age of 60 years. The former age limit is to apply also to the heads of the departments of obstetrics, gynecology, ophthalmology, otology, rhinology, and laryngology. The term of service, dating from the present reorganization, in all departments, shall be ten years. The three heads in medicine shall not engage in general practice, but shall confine their work outside of the hospital to consultations. The heads in surgery and in other departments shall strictly confine their work to their respective specialties. The departments of pathology and bacteriology shall be in charge of the professors of Toronto University in those branches. The department of anesthetics shall be under the supervision of one head. All public ward patients are to be under the heads of the different services and available for clinical instruction of students of Toronto University.

There is a probability that in the Province of Ontario legislation will shortly be introduced requiring medical inspection of all children attending public schools. The value of preventive medicine is generally admitted and the deliberations of the Congress held on the subject of school hygiene in Great Britain during the past year have awakened fresh interest in this country. The necessity of making more careful study of the physical and mental characteristics of each child and preserving records in regard to the same is acknowledged. To the defective construction of schools, particularly in reference to ventilation, heating, and lighting, is ascribed many of the causes of sickness in childhood. It is urged by the advocates of medical inspection of schools that a system can be adopted that will early detect the usual diseases and provide steps for preventing the spread of such by tracing out and correcting the causes of the conditions complained of. Montreal was the first city in Canada to move in this important matter and the results of medical inspection there indicate how necessary and useful such legislation would be if made to apply to a whole province. It is felt that if Ontario leads in this important matter the other provinces of Canada will follow.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

DEATHS OF LASSAR AND HOFFA—SEMEN AND DARK FIELD ILLUMINATION—OPERATIONS ON THE LUNG—TUBERCULIN REACTIONS.

BERLIN, January 18, 1908.

WITH the new year the Berlin Faculty has sustained two serious losses which have been all the more deeply felt since the dead were taken while still actively engaged in their lifework. Oskar Lassar was the victim of a street accident and Albert Hoffa died while apparently in the prime of life as the result of an insidious heart and kidney disease. The achievements of the world renowned dermatologist, Lassar, and the no less celebrated orthopedic surgeon Hoffa, are too well known for me to attempt to describe them in this place, but a word may be said in regard to their work in the field of public health. Lassar founded a clinic and polyclinic for skin and venereal diseases which was supported entirely from his own private purse, and this at a time when no other such enterprise had been undertaken. He was always ready to offer his lecture room for the meetings of societies, and was vitally interested in furthering the foundation of public baths. He organized the German Society for Public Baths which has enabled every dweller of the larger cities to take a complete shower bath at any time of the day or year for the sum of 10 pfennigs (two and one-half cents). Until his death he was the president of the society and its most active member. He was particularly fitted for the work of organizing large assemblages and there have been few medical congresses in Berlin to the success of which Lassar did not greatly contribute. Hoffa's public services have been closely connected with his specialty of orthopedic surgery. He was especially interested in the matter of providing suitable means of support for individuals partially incapacitated as the result of accidents, and for cripples. The institutions for the treatment of bone and joint tuberculosis also received his ardent support, and the Cäcilienheim in Hohenlychen—named after Crown Princess Cecelia—was largely the result of his efforts.

The Berlin Medical Society, which is by far the largest of the medical societies of the capital, has again almost unanimously elected Senator president. From the last

session of the preceding year mention may be made of a demonstration by Posner relative to observations on human semen with dark ground illumination. This is noteworthy on account of the new method of examination. On the dark field the actively moving spermatozoa are to be seen as shining white bodies against the black background. A new feature seen by this method is that the middle piece is surrounded by a number of filaments with spherical enlargements. These filaments which in less distinct form have already been seen by Benda and described by him as the true organ of motility, can be detected only on perfectly mature spermatozoa. In specimens obtained by puncture from an individual suffering from azoospermia this structure could not be demonstrated.

In the session of January 8, W. Koerte spoke on resection of the lung for bronchiectatic cavities and presented patients who had been operated on successfully. He considered that there was no use in opening only a single cavity as the suppuration persisted undiminished in the others. Two difficulties were to be overcome in the diagnosis. Productive pneumonias in the *x*-ray pictures appeared as shadows and could therefore readily be mistaken for abscess cavities, and, furthermore, in some cases pulmonary abscesses might be mistaken for bronchiectatic cavities. From the prognostic standpoint it was necessary to differentiate clearly between these conditions, for in twenty-eight cases of pneumonotomy for abscess and gangrene twenty recoveries had resulted, while in fifteen performed for bronchiectasis only four cures were effected. A reasonable outlook for cure was afforded only if the bronchiectatic condition was limited to a single lobe of the lung. It had been found best to obtain free access to the lung by resecting two ribs, and in this way enough room was gained for subsequent operations. The mucous membrane in the neighborhood of the hilus of the lung was very sensitive and contact with it caused attacks of coughing. If simple opening of the foci did not result in cure, at a second operation further resection of the ribs and pulmonary incisions were resorted to in the hope that the resulting pulmonary shrinkage would lead to permanent cure. Only in case these measures had proved unsuccessful was resection performed. A boy of eight years was demonstrated whose lower lobe and half of the middle lobe had been removed. Difficulties encountered at the operation were deep-seated hemorrhage and irritation of the vagus leading to respiratory and cardiac symptoms. Sauerbruch's cabinet, in which the operation was performed under reduced pressure, was not necessary, as pneumothorax was not greatly to be feared. Early operation was to be recommended in every case, though the patients always opposed the suggestion.

Every number of the German medical journals contains a contribution on the cutaneous tuberculin reaction of von Pirquet, and the conjunctival reaction introduced by Calmette. An interesting paper was read by Stadelmann and Wolff-Eisner on this subject in the Society of Internal Medicine. Stadelmann first described the typical course of both reactions with especial reference to the late reaction. Except for a slight lymphangitis in isolated cases, no drawbacks to the procedures had been noted. In clinically certain tuberculosis a positive reaction was obtained by both methods. In advanced cases the reaction became weaker the more serious the condition. In the course of the observations it was found that a negative reaction was prognostically unfavorable. Of patients in the second stage of the disease five passed into the third stage and of fifteen in the third stage fourteen died. This feature of the reaction might be found useful in selecting patients suitable for sanatorium treatment. Clinically the conjunctival method was superior to the cutaneous one, not only because more readily carried out, but also because in the presence of latent foci it was negative. Furthermore, one-half of all healthy persons reacted to the cutaneous method, while only a sixth responded to the conjunctival test. Repetition of the test was of no advantage. The speaker in closing claimed for his collaborator Wolff-Eisner priority in regard to the conjunctival reaction, for this observer immediately on von Pirquet's announcement had hit upon the idea of testing the reaction to tuberculin in the eye.

Will of Baroness De Rothschild.—By the will of the Baroness Adolphe de Rothschild, who died a few months ago, more than $1,600,000 is given to charity. Among the objects for which the money is to be used are a maternity hospital, an establishment for providing pure milk for infants, and refuges for orphans and working girls.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ORTHOSTATIC ALBUMINURIA—PLEURITIC EXUDATION—TUBERCULOSIS OF THE HIP—PROLAPSE OF THE RECTUM.

VIENNA, January 15, 1908.

LUDWIG JEHLE, Prof. Escherich's assistant, has reported on observations on orthostatic albuminuria during childhood, a condition of which the etiology is still uncertain. Six children under Jehle's constant observation excrete albumin only while standing but not while walking or running, or when seated in a perfectly upright position resembling that of standing. The excretion is most abundant while kneeling but is absent if the child while in this position sits on its heels. In these changes of position the kyphosis of the lumbar spine is converted to a lordosis and as soon as this takes place albuminuria at once results. If the patient stands bent forward slightly there is no albumin in the urine, but it immediately appears when the child assumes the vertical position. When Jehle fixed the body in the bent position by means of a neck band fastened to a pelvic belt no albumin excretion followed in spite of days of walking and standing, but it immediately resulted when the restricting band was removed. A child was placed in a plaster jacket while standing and then put to bed, with the result that the albumin excretion continued. The lordosis therefore appears to be a causative factor of orthostatic albuminuria, and probably a definite variety of lordosis, having its greatest curvature not at the third and fourth lumbar vertebræ as is customary, but at the first and second. Jehle believes that this is a result of a weakness of the lumbar musculature in delicate or convalescent children, and that the lordosis either directly or indirectly causes kinking of the renal vessels leading to interference with the circulation of the organ which results in the excretion of albumin. An anatomical lesion of the kidney cannot be present since the albuminuria ceases at once on correcting the lumbar lordosis.

Hermann von Schrötter observed a patient with unusually freely movable pleuritic exudation. Three years before he had suffered from fluid on the right side which was frequently aspirated. At present, examination revealed an exudate limited in the sitting position by the angle of the scapula posteriorly and in the right axilla by the fifth rib, while on lying down dullness began only at the fifth interspace. The case was one of very freely movable fluid, a condition that was apparent also on *x*-ray examination. When the patient was laid on the left side it could be seen that the exudate moved downward toward the mediastinum, the diaphragm and lung becoming clear so that the latter enlarged on inspiration while the diaphragm descended.

Prof. von Hacker of Graz resected the hip for tuberculous disease in a patient of twenty-four years. The wound was closed entirely after the introduction of iodoform glycerin emulsion and in fourteen days was completely healed by first intention. The condition had lasted for three years and had presented typical symptoms. Three months after the operation the patient was able to walk without pain by the aid of a plaster-of-Paris dressing. In the fifth month she began to walk without any dressing whatever. Externally the hip hardly appeared altered and flexion and extension, and adduction were possible to a considerable degree, rotation to a smaller extent. Shortening was 4 cm. A radiograph showed the acetabulum filled with iodoform while the stump of the neck of the femur was in a position of slight abduction opposite to the upper edge of the acetabulum. The operation fully met with the expectations, and showed that under favorable conditions resection of the hip could be made to heal by first intention without drainage even when performed for tuberculosis.

Bittner of Brunn effected a cure in two cases of prolapse of the rectum in children in which he operated in a manner similar to the procedure of Thiersch by subcutaneous narrowing of the anal ring by means of a strong silk suture. Both children were two years of age and for many weeks had suffered from rectal prolapse of considerable intensity. The rectum descended for ten to twelve cm., especially on defecation, while the sphincters were much relaxed. After all the customary bloodless procedures had failed the following plan was resorted to. The children were prepared for several days by being kept in bed on a scanty fluid diet while the rectum was frequently emptied. On the day before the operation the child was given nothing but tea, the intestine was again thoroughly emptied, and a little opium was administered. Before the operation the rectum was packed and the operative field carefully cleansed. A small incision was then made through the skin in front and behind the anal ring. By means of a strong curved needle a heavy silk thread was

drawn from the anterior incision subcutaneously to the left of the anus to the posterior one, the needle being again inserted and the thread caused to emerge from the original opening after having passed to the right of the anus. The thread was then gradually tautened while an assistant with his finger in the rectum controlled the degree of constriction. The thread was tied and buried, the two incisions were closed by suture and the tampon was removed from the rectum. After the operation another dose of opium was given and the child dieted for five days. The sutures were then removed and the bowel well cleared out by means of castor oil. The result was very good, a permanent cure being effected. Bittner used a silk thread instead of a silver wire since the former is ultimately absorbed and therefore does not require removal. The procedure is simple and would probably suffice in most cases of rectal prolapse of children.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 13, 1907.

The Control of the Lymphatics in Infection of the Extremities.—H. L. Burrell speaks of the usefulness of compression of the lymphatics and modification of the blood stream as a neglected but useful measure and of paramount physical importance in assisting nature to combat destructive poisons. He wishes to warn against making an incision in an acute local infection until nature has established or there exists an adequate resistance in the tissues of the individual against toxemia. When incisions are made in a patient who has no resistance, the mildest infections may become virulent. The author advises the following method of procedure: A local dressing is first placed on the source of the infection, which is usually on the finger or hand. Rolls of oakum are then placed in position over the course of the arteries and are secured lightly in position by a gauze bandage which is applied from the finger-tips to the axilla. Care is now taken to make equable compression from the finger-tips up to the axilla, an attempt being made to control the circulation in the limb by compression of the oakum rolls. The circulation in the limb unquestionably may be controlled by a skillfully applied dressing, for pain and throbbing will soon cease. At the end of eight hours, instead of taking off the bandages and re-applying the dressing, another bandage is superimposed, so that it gathers up the slack of the dressing. This rebandaging is repeated every six to twelve hours for three to five days. Increased pain or increased tenderness in the limb or a marked elevation of temperature indicates that the dressing must be changed. However, as a rule, when the dressing is removed in three to five days, the limb will be found shrunken and wrinkled, the redness will have disappeared, and usually the original area of infection will be found localized, so that a pocket of pus may be incised and evacuated. This same compression treatment may be applied to the lower limb with equal efficiency. In the early stages of an infection, particularly if the lymphatics are conspicuously involved, a compression dressing is of great value in controlling the spread of the infection and in preventing all but a very mild toxemia. The pressure applied is sufficient to control the circulation of the lymph and blood in the extremity but not enough to stop it.

New York Medical Journal, February 15, 1908.

Some Observations on the Removal of Adenoids.—M. J. Ballin gives a general review of the adenoid question and figures the curette which he prefers. His general conclusions are: (1) That the operation can be easily performed without any anesthetic, taking from one to three minutes. (2) That the growth comes away *en masse*, thus leaving no rests behind which are later the source of so-called recurrences. (3) That by examining the growth we can ascertain if a portion of it is still retained, and its location; and in addition we can show the mass to the parents, thus demonstrating the cause of the impaired nasal respiration, and pointing out the necessity of operation. (4) That complete removal leaves no rests behind, which later swell up and become hypertrophied, thereby bringing about symptoms similar to those prior to the operation, or so called recurrences. (5) That by carefully examining the pharynx immediately after operation we remove pending pieces which would otherwise become infected, and lastly, (6) That these pending pieces of tissue are generally the cause of postoperative hemorrhages, and through their breaking down and becoming infected give rise to a secondary suppurating otitis media, with all its sequelæ, to the rigidity of the neck, enlargement of the glands in the neck, nausea, vomiting, general malaise, and a rise in the temperature.

Psychasthenia.—By this term, originally suggested by Janet, J. Collins refers to a disorder characterized by mental, emotional, and physical symptoms made up principally of obsessions or inoperative concepts, fears, doubts, anguish, uncontrollable movements, enfeebled will power and some or all the customary physical symptoms of neurasthenia. He gives a detailed history of one personal case, that of an unmarried woman of 32 years. Concerning her symptoms he notes that they practically fall under three heads. Obsessions, peculiar movements, which she calls uncontrollable, twitchings of different parts of her body, agonizing emotions and manifestations of psychological insufficiency, sentiments of unreality, of somatic strangeness, and of depersonation, and finally diminution of will power. The obsessions are involuntary, automatic, and irresistible. They come into her mind without the slightest warning and take possession of it. The only relation between their occurrence and any outside factor is what has been noted in regard to fatigue. The patient makes her best effort to prevent them or to circumvent their dominant operation, but she accomplishes little in this direction. She realizes how strange and morbid the obsession is and how contrary to her nature and thought the obsessive ideas are, and she is able to discuss them in an impersonal way, but this has no effect upon the tenaciousness of the obsession, nor can she shut it out by effort of will. The various uncontrollable twitching movements, which are to be interpreted as manifestations of psychological operation upon the motor areas of the brain despite the action of the will, seem also to occur much more severely and extensively when she is fatigued or when anything has occurred to lower physical or mental vitality.

Management of Febrile Conditions After Abortion and Labor.—A. Brothers divides such cases into the following classes: 1. Fever due to retention of infected placental débris or blood clots. Irrigation and if necessary the blunt curette. 2. Fever due to pelvic inflammation. As a rule such cases recover after local abdominal refrigeration, prolonged rest in bed, and hot vaginal douches given at short intervals. If there is evidence of local suppuration, wait for "pointing" if possible; laparotomy is sometimes necessary to reach a pus pocket. 3. Fever due to bacteriemia (septicemia). Here the author believes that the treatment of the future will take into consideration the earliest possible removal of the uterus in the hope that the system may still have sufficient resistance to fight off successfully the beginning systemic bacterial invasion. The use of opsonins here as well as of the antistreptococcus serum has not thus far offered particularly promising results. 4. Fever due to general peritonitis. If such a condition shows a tendency to subside rapidly under the use of ice to the abdomen, it may be well to wait in the hope that the process will go on to complete recovery or that pus formations will become localized. On the whole, given a positive diagnosis of puerperal peritonitis with the patient in fair condition, the author thinks that a laparotomy in proper hands offers her a better chance for her life than if nothing is done.

Vaccination in the Far East.—C. S. Braddock, who was formerly the chief medical inspector of the Siamese government, describes the occurrence of smallpox in Siam and calls the attention to its still prevalent ravages in the Eastern countries. Stimulated by the success of the United States in Manila, the Siamese authorities sent a representative to study American methods, and after his return and a long series of experiments an efficient vaccine was finally produced and vaccination of the Siamese was systematically begun. The results were as they always are, most gratifying. In the extension of this work most valuable allies have been found in the American missionaries. The author gives the following superstition of the Siamese people as to the origin of variola. "There is a great giant that lives in the sky and who has seventy-six sons and daughters; each one of these is a variety of (Fidat) smallpox. When the giant sends one of them to earth and he visits the individual, that individual has that variety of smallpox, one of the seventy-six the Siamese divide the disease into."

Journal of the American Medical Association, February 15, 1908.

The Problems of Sanitation.—E. C. Jordan says that up to the present, sanitary measures have affected chiefly the infectious diseases, but it is evident that further information is needed before we can intelligently plan a campaign against disease. Even as regards typhoid fever, which has been so much reduced by sanitation, there are still points to be learned and how much do we really know, he asks, about the best methods of preventing summer mortality among infants in large cities. In England, the infant mortality has not been materially reduced dur-

ing the last twenty-five years though the general death rate has materially decreased. Germany, however, shows a steady reduction and in this country while the data are very incomplete, owing to our imperfect vital statistics, the figures in two large cities, Boston and New York, also shows a progressive decrease. Hygiene is becoming more and more a social question and under this particular head he mentions industrial hygiene, the protection of workers in dangerous or unhealthy occupations and education in public hygiene, as living questions of the day. More men should prepare themselves for public health work and greater facilities should be offered by medical schools in this particular line. The medical profession can itself do much to bring about a proper valuation of the work done in this field.

Pregnancy as a Cause of Dental Disease.—J. E. Power remarks on the neglect of the oral cavity by pregnant women and its consequences, and the necessity of the physician insisting on the proper hygiene of the mouth during pregnancy. In this condition, the natural degenerative processes, together with lessened resistant capacity, may cause complete destruction of the teeth with consequent bad effects not only on the patient's own health, but also on that of her offspring. This is especially a time for her to consult the dentist and insure a normal condition of the teeth, so far as that is possible. It is Power's custom in these cases to make a thorough physical examination of the patient so as to adapt the measures employed to her capacity of enduring the strain incidental in all dental operations; then to extract all broken down roots under local anesthesia, as possible sources of trouble, to clean the mouth thoroughly and make arrangements for future monthly inspections which will enable him to attend to any conditions that may arise and will tend to cause the patient herself to take due care of the teeth, knowing they are going to be inspected. Vomiting of pregnancy, whatever be its cause, has a bad effect on the teeth, and Power advises special care taken to neutralize the acidity of the mouth after each vomiting, and also during the interval. In case of toothache during pregnancy, he advocates the extraction of diseased teeth, treatment of which might be attended with pain sufficient to affect the life of the embryo and possibly also that of the mother in this condition. Under anesthesia, local preferred, and with modern technic, it can be safely done. It is advisable to avoid it at times corresponding to the menstrual period on account of the greater risk then of abortion. Great care should be exercised in diagnosing the source of dental pain, as often disease in other organs may thus manifest itself and treatment or extraction of an apparently aching tooth may complicate rather than simplify the case

Posture and Blood Pressure.—A. A. Sanford reports the results of a study of the effects of posture on the blood pressure, with special reference to the relation of the pressure conditions in the upper and lower portions of the arterial tree in different positions of the body. His methods and instruments are described in detail and his findings summarized substantially as follows: 1. By carefully noting the pulse changes as compression is slowly applied, not only is the point of obliteration noticeable, measuring the systolic pressure in the vessel, but also the point of diminution in the amplitude of the pulse or the diastolic pressure is to be observed; and, furthermore, in many instances, a marked oscillation occurs in the mercury column at and above the point of diastolic pressure. 2. Posture affects both systolic and diastolic pressure There is an increase in the arm in changing from the erect to the sitting, supine and head down positions, and at the same time a corresponding decrease in pressure in the leg. With these is a marked decrease of pulse rate. 3. The pulse pressure, or difference between diastolic and systolic pressures, increases in the arm and decreases in the thigh with changes from the erect to the sitting, supine and Trendelenburg positions. 4. At the heart level. Hs (heart strength) × Hr (heart rate) = a constant in all postures. Therefore, the pressure changes directly as the peripheral resistance. 5. In the sphygmomanometer we have a convenient means of applying a known amount of pressure to a limb, and thus can use it as a therapeutic aid in passive hyperemia treatment. 6. For accurate results the pneumatic arm band should be at least 9 cm. wide. Readings are from 15 mm. to 30 mm. lower than with the ordinary Riva-Rocci 5 cm. girdle. The width of the band should always be recorded

Subconscious Ideas.—E. W. Scripture describes the recently developed methods of discovering the subconscious ideas that influence the mental associations and underlie certain morbid conditions, such as hysteria and some forms of insanity. The method consists in observing the time required for the association of ideas and the character of associations produced. Association of ideas takes time; distraction of attention makes the time longer and also tends to make one forget what he has said. A selected list of words is used and the subject is asked to say quickly the first thing he thinks of when these words are singly called out to him, the object being, it is explained to him, to test his mental activity Each answer and the time it requires is noted and then the process is repeated with the request that the same answers be repeated so far as possible. In the record thus made, we look for associations showing one or more of several indications of distracted attention, namely: 1. Unusually long time; 2. forgetfulness, 3. superficiality (associations other than those connected with the meaning of the word). Jung, who has particularly developed this method, adds to these: 4. Mistakes—no answers; 5. word is taken in some unusual meaning explainable only by the presence of some disturbing thought; 6. persistence of the disturbance for following associations. Experience has shown that when a word brings up an idea associated with an emotion this distracts the person so that he does not pay full attention to what he is doing, and this shows itself in the record in one or other of the above ways, and this often lasts for several following associations. Illustrations of this from actual experiments are given. In this way it is possible for an outsider to discover our disturbing emotions against our will. In a purely medical point of view the most interesting fact of this study is its therapeutic application to hysteria, which is very largely due to emotional strains that leave their impress on the subject's mind. The idea or group of ideas connected with a strong emotion is here called a complex, and if we can discover the complexes causing the patients hysteria and get her to talk freely about them, according to Freud of Vienna, we can in many cases produce a cure. Just how this is effected is not quite clear. We may perhaps assume that the continual hauling of the complex into the limelight deadens it, or that the patient tires of it from repetition, but, however this may be, marked cures are said to be brought about. The use of the method for the detection of crime is also noticed and an instance reported by Jung is given. Although any physician can learn to apply the method, it requires considerable time and skill and accurate time measurements. Eventually, Scripture says, we may expect to have specialists to whom the patient is sent for a mental analysis, but to be returned for treatment.

Polioencephalitis Superior.—W. A. Holden and Joseph Collins remark that while many of the diseases dependent on acute pathological conditions in the gray matter of the central nervous system have been long known to medical literature, that known as polioencephalitis superior, inferior ophthalmoplegia, or superior bulbar paralysis has received recognition only for about a quarter of a century, having been first described by Wernicke in 1881. While his teachings as to its dependence on alcoholic intoxication and its fatal termination were at first generally accepted by the profession, it is now commonly believed that the underlying morbid condition is not unlike those constituting the pathological processes in various other inflammations of the central gray matter, and that the causes that are responsible for such inflammations elsewhere in the central nervous system are responsible for this disease. Alcohol, however, is probably the most important factor, though other intoxications and certain infectious diseases have had a good case made against them. That it is not always fatal has been clearly demonstrated. Mild attacks with complete or partial recovery are not so rare as has been supposed. When the inflammation is confined to the gray matter of the third ventricle, the symptoms are few and as distinctive as in anterior poliomyelitis, but when it extends to the fourth ventricle and beyond, the clinical picture becomes more complex and a satisfactory diagnosis sometimes can hardly be made. In some cases the structural lesions found on postmortem are slight and entirely out of proportion to the severity of the symptoms observed. These cases are looked on as analogous to those of asthenic bulbar paralysis (bulbar paralysis without anatomical foundation) in which it is supposed that several levels of the different segments of the central nervous system are so overwhelmed by some toxic agent as to render them partially or wholly functionless, though not so as to leave discernible evidence in their cells. There may also be intermediate cases with trifling lesions.

Fulminating Pelvic-Abdominal Edema Simulating Tubal Pregnancy.—W. A. Briggs reports two cases, one of them fatal, in which the symptoms justified the diagnosis of ruptured tubal pregnancy, but which proved to be on operation cases of fulminant edema of the pelvic connective tissue. He has been able to find but two similar cases in medical literature (those of Jocet and Le-

gueu), which he reproduces. His conclusions are given as follows: 1. Fulminating pelvic edema may very closely simulate ruptured tubal pregnancy. 2. Absence of subjective and objective signs of pregnancy, of irregular uterine hemorrhage, of decidua in the flow in cases of shock with severe pelvic pain, would suggest the possibility of fulminating pelvic edema. 3. A hemoglobin test might assist in the differential diagnosis. 4. Fulminating pelvic edema is probably angioneurotic in origin. 5. Death (as in Case 2) may result from acute pelvic-abdominal edema. In both his cases, there was a mild inflammatory condition—in the non-fatal case producing agglutination of the peritoneum and roofing in the pelvis, and in the other confined to the right adnexa. The second patient was decidedly neurotic.

The Lancet, February 3, 1908.

Phosphaturia and the Treatment of Disease by Conversion.—R. Harrison notes that it has not infrequently been observed that in chronic urethritis, the urine has become altered in character and assimilated with that known as phosphaturia, the change occurring irrespective of any internal medication, and further that when this change was observed the cessation of the discharge or gleet, as it is commonly called, for which the patient had originally come under treatment, usually soon followed, either spontaneously or by treatment appropriate to the phosphaturic state without apparent reference to the cause which preceded it. This casual observation raised the question whether it was possible that there was any relationship between this incident and what followed, whether, in fact, the phosphaturic state of the excretion was inimical to the existence of the infecting bacillus. The observation was made so frequently as to suggest this, and led to the systematic examination of the urine and other discharges for gonococci in all persons coming under treatment for gleet more carefully and frequently than previously. From them the following conclusions appeared to be grounded. 1. That in a considerable number of instances thus designated and of undoubted specific origin there was no evidence at the time of examination that there was anything wrong with the urine or with any urethral discharge complained of inconsistent with the phosphaturic state alone. This condition was either apparent to the eye on allowing the urine to stand for a short time in a glass vessel or was evidenced by boiling the excretion when any cloudiness which followed was immediately removed by the addition of nitric acid. Here any pus corpuscles which the microscope detected were physically explainable by the crystalline precipitates the urine contained and which were often present in sufficient quantities to give this excretion a semi-purulent or opaque appearance. How or when this phosphaturic transformation took place in the history of an ordinary case of chronic infecting urethritis was not always easy to determine. In many instances which were carefully tested and microscopically examined this change appeared to mark the concluding stage of gonococcal life and was also often coincident or nearly so with the adoption of such treatment as the phosphaturic state usually requires. Further, these examinations showed how easily and frequently phosphaturia may counterfeit and be treated for a specific urethritis and even be intensified by the remedies commonly used for the latter. 2. The second inference was that the artificial production and temporary continuance of a state of phosphaturia might be utilized in the treatment of specific gleety affections following upon gonococcal infections. To produce a urine having the prominent features of phosphaturia by the administration of alkalies—bicarbonate of potassium was generally selected for this purpose—is not a matter of much difficulty or of any detriment to the patient. The effect on the urine should be sufficient to render it responsive to the usual tests, microscopical and otherwise, by which phosphaturia is recognized, and not merely to produce an alkaline reaction to test paper. Further, it is necessary to maintain this condition for some little time, during which period all local applications should be suspended. It will usually be found after a period of ten days or so, and as the phosphaturic condition gradually passes off under the influence of altered treatment and diet appropriate to this state, that no signs will be found such as were previously complained of.

Hemo-Pericardium Associated with Syphilis.—J. L. Baskin reports the case of a man of 65 years of age who was partly demented. There were various stigmata of syphilis in different parts of the body. He did well on anti-syphilitic treatment, but on a certain evening while at the toilet he became giddy and fainted, and though he rallied for awhile he died in about half an hour. Among the lesions found at the autopsy was an enlarged heart weighing 11 ounces. The pericardium was distended with post-mortem clot. The coronary arteries were calcareous in character; the left one was ruptured one and a half inches from the aorta; at the seat of rupture was a small node of pale yellowish colored material which extended about one and one-fourth inches into the myocardial substance, which was hypertrophied, and around it the tissue was of fibrous consistency and tough under the knife. On the pericardial aspect the necrotic changes appeared to have involved the artery which lay on the gumma; the arterial wall, where ruptured, presented a star-shaped fissure. The aortic valve was thickened at the base of each cusp; the columnæ carneæ showed signs of fatty degeneration. The liver was congested. The author notes that signs of marked distention of the pericardial sac were found. At the time of the patient's collapse gentle percussion revealed dullness extending up into the second left intercostal space; the cardiac sounds were muffled and the respirations were stertorous in character; the pulse was imperceptible at the wrist. When found in the heart gummata are usually multiple and often of cartilaginous-like consistency; only the one described was found in this case. Reference is made to several similar cases which are recorded in medical literature.

Acute Ascending Paralysis with Recovery.—The patient of C. W. Vining was a muscular man of 24 years whose symptoms began four days before admission to hospital, with weakness in the calves of his legs. This progressed and later extended to his arms. He had fallen off a ladder on to his feet a week previously but had experienced no inconvenience at the time. From the time of his admission his symptoms developed in a typical manner. The case had run its course by the end of three weeks. The interest in the case centers in the fact of recovery from what appeared to be a severe instance of Landry's paralysis. The diagnosis lay between (1) diphtheritic paralysis, (2) Landry's paralysis, and (3) a toxic paralysis affecting the anterior cornua or nerves. There was, however, no evidence or history either of diphtheria or of any exposure to such toxic influences as syphilis, gonorrhea, lead, or alcohol, and on the whole the case seemed to correspond better with Landry's acute ascending paralysis than with any other disease. Against this diagnosis there might be urged (1) the anesthesia of the palate and the slight sensory disturbance of the legs, and (2) the fact that the parts affected were not altogether anatomically in succession from below upwards, but in Landry's own description of the condition diminution in cutaneous sensibility over the distal parts of the limbs is mentioned and the arms and face were affected before the legs were completely paralyzed. In the present case strychnine appeared to have a very beneficial effect.

British Medical Journal, February 8, 1908.

Migraine.—A general consideration of the subject is given by T. H. B. Dobson. Concerning treatment he says that it all hinges on the matter of lessening the tendency to explosive action in the nerve centers. Of obvious value are sufficient sleep, nutritious food (over-eating being most carefully avoided), prevention of intestinal fermentation and regular exercise. Common immediate exciting causes are gastric disturbance, constipation, and eyestrain, each of which suggests its own proper correction. Concerning the relation of migraine to epilepsy, the author lays down the following propositions: (1) In rare cases migraine alternates with epilepsy. (2) Migraine may develop into epilepsy. (3) The tingling sensation, which may come on in the finger and gradually pass up the hand and arm during the twenty minutes in which the fortification figures are developing in migraine, may also occur as an aura of epilepsy; but in this case it is only momentary. (4) Headache follows both; that of migraine being more severe. (5) The aura of migraine seldom affects a leg or the trunk. (6) Somnolence may occur in both.

Spleno-Medullary Leukemia and Splenic Anemia (Banti's Disease).—Histories of cases of these two affections are given by J. G. Taylor together with detailed blood findings which cannot be reproduced here. The case of spleno-medullary leukemia occurred in a woman who when first seen had complained for five months of increasing weakness, shortness of breath, and gradual swelling of the abdomen. Three or four times recently she had had "bruises" occurring spontaneously on her legs. She was anemic-looking, but with a flush over the malar bones. Physical examination revealed an enormously enlarged spleen, extending as far as the middle-line, and well below the umbilicus. There was no tenderness on pressure, or when lying down, but when standing or walking she complained of a dragging sensation. The other abdominal and the thoracic organs revealed nothing abnormal. The fundus of the eyes was normal. She had never had any hemorrhages except the spontaneous "bruising." She had no ascites, though this occasionally

occurs in spleno-medullary leukemia. This patient did well on arsenic and *x*-rays applied over the spleen. The effect of the former was definite and positive, but that of the latter doubtful. The case of splenic anemia was that of a man of thirty years who had complained of feeling unwell, but nothing definite, for three years or so, on and off. The onset was vague. Previously he had been a healthy man. At times he had had nose bleeding and a few attacks of hematemesis. Three weeks previously he had been tapped for ascites, not for the first time. Physical examination revealed a spleen which extended just below the umbilicus. Nothing abnormal could be detected in any other organ. The author discusses fully the questions of etiology, pathology, and symptomatology of this affection. As to treatment little is known. Most of the deaths in which splenectomy has been tried have been from hemorrhage.

The Use of Chemicals in Aseptic Surgery.—C. B. Lockwood notes that attempts are being made at the present time to conduct surgery without chemicals. He concedes that they may be harmful, but does not believe that we could get along without them. The great aim of every surgeon is to banish bacteria from the field of operation and from everything brought in contact therewith. While chemicals may not always sterilize the hands, they often do. Lockwood uses for the hands the 1-500 in spirit and biniodide of mercury lotion. Inexperienced assistants should wear rubber gloves, but he himself finds that they interfere with delicacy of touch, especially in cases of abdominal surgery presenting adhesions which have to be overcome. The use of gloves is under no circumstances a justification for the lessening of hand disinfection. They are however indispensable for septic operations and septic dressings. The same general principles apply to cleansing the patient's skin. There are in addition other sources of wound infection. The air of our cities, dwellings, and hospitals has in it bacteria from the skin and air-passages of human beings and from the alimentary tracts of men and animals. If during an operation any bystander coughs or sneezes it is safe to assume that the wound is bombarded with bacteria. All the paraphernalia of modern surgery must be worked by erring men and erring women, but the author knows of no better method of minimizing the inevitable dangers than by the present general methods of chemical solutions applied in the right way, at the right time, and in the right place.

Rigor Mortis in the Stillborn.—Four cases are reported by C. H. Watts Parkinson, whose conclusions follow: (1) Rigor mortis may set in under certain conditions before labor, and may pass off while the child is still *in utero*, and possibly may delay the birth in these cases until it has passed away. (2) Rigor mortis may set in when the child dies during labor, and may either be complete before or may go on to completeness after birth, and in these cases increases the difficulty of expulsion. (3) A child may die during labor and be expelled before rigor mortis can set in, but rigor mortis may supervene after birth more or less completely. (4) The attitude produced by rigor mortis in stillborn children differs from that produced by cadaveric rigidity under ordinary circumstances and by its character enables an opinion to be given that the child had no separate existence, for in every such case the limbs and body generally become drawn into the position in which it lies normally in the mother's womb. Rigor moritis *per se* is not a sign of live birth, but its character enables one to decide whether or not the child was stillborn.

Berliner klinische Wochenschrift, February 3, 1908.

The Surgical Treatment of Chronic Dysentery.—Steiner describes two cases of very severe and long standing dysentery which proved refractory to all medical treatment and were finally relieved by the formation of an artificial anus at the ileocecal junction. This was made in such a way as to cause all the feces to be discharged through the opening without entering the colon. At the same time copious daily irrigations of the intestine from the rectum to the cecal opening were practised, five or six liters of water being run through and then one or two liters of an astringent antiseptic solution. In one case these irrigations were kept up for seven and one-half months and in the other, for two months. After it had seemed probable that all the ulcers had been healed, and that the large intestine had been brought back to a normal condition, the capacity of the gut to stand the passage of feces was tested by plugging the artificial anus and returning the fecal current to its natural channel. After sufficient time had elapsed to show that the colon was again capable of performing its functions the artificial anus was closed by operation. In each case the cure has been a permanent one. The author prefers this method to that of making the artificial anus in the left flank as this does not permit the entire colon to be treated, and to the method of appendicostomy, as this does not cause the feces to be discharged externally and so afford the necessary rest to the colon.

Münchener medizinische Wochenschrift, February 4, 1908.

A Diagnostic Skin Reaction With a Tuberculin Ointment.—Moro has found that a specific reaction may be induced in tuberculous subjects by means of inunction with an ointment containing tuberculin. For this purpose he uses an ointment of anhydrous lanolin containing 50 per cent. of old tuberculin. When kept in the ice box the preparation retains its efficiency for months, and 10 g. is sufficient for about one hundred tests. The application is made to the skin of the abdomen just below the end of the sternum, or if this is not free from cutaneous lesions the neighborhood of the nipple is used. A portion of the ointment the size of a pea is rubbed in with the finger, using moderate pressure for a half to one minute. The area treated measures about five centimeters in diameter. The skin is left uncovered for about ten minutes but no dressing is applied. In negative cases the skin showed no reaction but in others a positive result was manifested by the appearance of an eruption of papules at the site of inunction. Three grades of this are distinguished. (1) A weak reaction in which from two to ten solitary, small, pale papules appear in twenty-four to forty-eight hours and vanish again in a few days. (2) Medium reaction, in which in the course of the first twenty-four hours up to one hundred or more miliary or larger red papules which may measure three millimeters in diameter appear. The skin in the neighborhood is moderately reddened but the eruption is confined to the site of inunction, itches slightly, remains unchanged for several days, and then slowly fades. (3) Strong reaction, shown by the appearance within a few hours of very numerous red papules with inflammatory base and accompanied by itching. There is exudation into some of these lesions which may measure five to eight millimeters in diameter; the eruption is not confined to the site of inunction but extends to the surrounding parts. In a few days the papules dry up and become scaly and in two weeks nothing is to be seen except a brownish pigmentation of the skin. None of the forms of reaction is accompanied by general symptoms or elevation of temperature. The author believes that the reaction is strictly specific though somewhat less sensitive than the von Pirquet cutaneous reaction or the ophthalmo-reaction. Its value as a diagnostic measure must be determined by further observations in a large series of cases. The method has the great advantage of being entirely harmless, even the itching at the site of inunction being a comparatively rare occurrence.

Artificial Respiration by Ventilation of the Trachea.—Volhard has found that it is possible to keep alive curarized animals in whom all respiratory motion has ceased by allowing a stream of oxygen to flow into the trachea through a tube which does not fit quite tightly. The animals live for one and a half to two hours without any movement of the chest wall, but then regularly die. This result is due to CO_2 poisoning although the blood remains bright red in color, the diffusion of gases in the bronchi not being sufficiently active to eliminate all of the CO_2 given off though the interchange does go on to some extent, as is shown by the fact that the animals live one and a half to two hours. Volhard has devised an apparatus by means of which this method can be practically applied, a rhythmical distention and collapse of the lung being secured by the use of the principle of the inertia of mercury. This device has been tried on a human being with good success. The patient suddenly ceased to breathe while being operated on for a cerebral abscess and after three hours of ordinary artificial respiration Volhard's apparatus was set in operation and functionated satisfactorily during nine hours more, at the end of which time the patient died as the result of the extensive softening in the region of the brain abscess.

Cleaning Instruments.—To remove coating from instruments which have been boiled use of prepared chalk, ammonia, and alcohol each 2 parts, water 4 parts. Rub the instruments with a cloth saturated with this solution, then rub them dry with another cloth.—*Dental Cosmos.*

Gonorrhea in Women.—Cases of concealed gonorrhea in women may be detected by pressing the anterior wall of the vagina against the urethra. This will empty the urethral (Skene's) tubules and bring to light a very small quantity of pus which is gonorrheal.—*American Journal of Dermatology.*

Book Reviews.

Traité Clinique et Thérapeutique des Maladies de l'Appareil Respiratoire. Par G. Carrière, Professeur agrégé a l'Université de Lille; Chargé des Cours de Clinique Médicale des Enfants et de Thérapeutique; Lauréat de l'Académie de Médecine. Deuxième édition, revue et augmentée. Paris: Vigot Frères, 1908.

The author has limited his subject to the clinical pictures and the therapeutics of the diseases of the respiratory tract. Taking full advantage of the space thus gained, he enters fully into the etiological factors of each disease; gives well balanced descriptions of the clinical phenomena, describing them from the standpoint of the observer at the bedside, rather than of the laboratory or the scientific worker; the necessary pathological and bacteriological data he gives briefly, putting them, with a few historical notes on each disease, in smaller print than that of the main body of the work. He allots ample space to the subject of prophylaxis, and under treatment he attempts in every case to formulate the indications and the results aimed at. All together, the author has succeeded in writing a very practical statement of the symptomatology, the diagnosis, the prophylaxis, and the treatment of the diseases of the respiratory system, in the easy, conversational style of the lecture. This second edition, moreover, shows careful attempt to bring the book up to date; for instance, both the cuti-reaction of von Pirquet and the ophthalmo-reaction of Calmette are given considerable space.

There are, however, some obvious faults in the book, and one of them is the complimentary use of personal names in the description of the clinical phenomena. Such designations as "Freud's sign," "Grancher's sign," "Frenet triad," etc., only burden the mind of the reader with unnecessary and unassociated names. The anatomists are struggling hard in reforming the illogical nomenclature that has resulted from a similar practice, and writers in other medical fields ought not, at least, to add further to the chaos in their own departments. Under treatment it is surprising that the use of tuberculin in pulmonary tuberculosis is not even mentioned. Few American physicians, too, would share the very conservative attitude of the author toward thoracocentesis in pleurisy with effusion; he recommends tapping the chest not before ten days after the appearance of the effusion. The operation has proved to be so little dangerous, and so directly curative, that waiting for a possible spontaneous absorption of the fluid, in the absence of any contraindications to the tapping, can hardly be defended. Finally, the book before us, in common with many others issued in Europe, lacks an index, nor is the table of contents such as to make up for its absence.

The Treatment of Fractures. With Notes Upon a Few Common Dislocations. By Charles Locke Scudder, M.D., Surgeon to the Massachusetts General Hospital; Lecturer on Surgery in the Harvard University Medical School. Sixth edition, thoroughly revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1907.

The continued popularity of Dr. Scudder's book may be gathered from the fact that two reprints and six new editions have been required in six years. The present edition, among the new matter, considers the fractures of the skull met with in obstetric practice and the remote results following trauma of the head; the arguments for and against operative procedures in the fractures of the patella, of the spine and of the hip are given at length; pathological fractures are discussed in a separate chapter. Dr. Codman's suggestive article on "The Röntgen Ray and Its Relations to Fractures" has been retained, and the book closes with the consideration of a few dislocations. Many new illustrations have been added, raising the total number to 856 photographs, *x*-ray pictures, and diagrams. The book retains its place among the foremost treatises on its subject in the English language.

Tropical Diseases: A Manual of Diseases of Warm Climates. By Sir Patrick Manson, K.C.M.G., M.D., LL.D. Aberd., Fellow of the Royal College of Physicians, London; Fellow of the Royal Society; Honorary D.Sc. Oxon.; Lecturer in the London School of Tropical Medicine; Physician to the Seamen's Hospital Society, etc. Fourth edition. New York: William Wood and Company, 1907.

Ten years ago a new edition of a work on tropical medicine would have aroused little interest in this country where the diseases of hot climates were encountered only along the southern borders of the United States and in the principal seaports. Now, however, that we have assumed "the white man's burden," the subject is of practical interest not only to those practising in our tropical possessions, but to every physician in the country who is likely to meet examples of such maladies in the person of some discharged and invalided soldier or of some returning visitor from the Philippines or from the West India Islands. Manson's book from the first took its place as an authoritative work on the diseases of hot climates, and the succeeding editions have established it more firmly as a classic. The present edition is considerably enlarged in order to keep pace with the rapid advance in our knowledge of these most interesting diseases, the principal changes and additions being in the section dealing with the fevers. Perhaps the most striking change to be found in this edition is the placing of blackwater fever in a separate nosological niche apart from malaria. Whether this is justifiable or not is questionable; the association of malaria and hematuria is so firmly fixed in the minds of tropical practitioners that this violent separation of the two will be regarded as premature if not unwarranted. The subject of trypanosomiasis has been entirely rewritten, and sleeping sickness has been transferred to this section, the previous speculation as to its causation having been shown to be erroneous. The section on animal parasites has also been enlarged and revised, and an appendix dealing with the hemoprotozoa has been added. This includes a useful, though tentative, classification of the protozoa by Sambon. The work is freely illustrated with 241 figures in the text and 7 colored plates. The book is convenient in size, well printed, and free from typographical errors. It is without a rival in its special field and can be confidently recommended to every one who through necessity or choice would familiarize himself with the diseases peculiar to the tropics.

Cancer of the Womb; Its Symptoms, Diagnosis, Prognosis, and Treatment. By Frederick John McCann, M.D. (Edin.), F.R.C.S. (Eng.), M.R.C.P. (Lond.), Physician to In-Patients, Samaritan Free Hospital for Women, London; Lecturer on Gynecology, Medical Graduates' College and Polyclinic, London; Honorary President Section of Obstetrics and Gynecology, Fifteenth International Medical Congress, Lisbon, 1906. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1907.

In this book the author gives a concise account of our present knowledge of cancer. He describes fully both the macroscopical and microscopical appearances of the different varieties of cancer, illustrating his text by forty-six plates. In discussing the etiology of cancer, the author says that the trend of modern opinion is against the parasitic theory. He divides cancer of the uterus into cancer of the neck and of the body, and subdivides cancer of the cervix into one originating from the vaginal portion and the other originating from the cervix proper.

The operations of vaginal hysterectomy, abdominal hysterectomy, the combined abdominal and vaginal hysterectomy and the extended or radical abdominal operation are described in detail. Space is also devoted to the post-operative treatment, and to the treatment of inoperable uterine cancers.

In considering the diagnosis of cancer, due stress is laid upon the occurrence of hemorrhage and a serosanguineous discharge. In speaking of the symptoms of pain and a foul-smelling discharge, Dr. McCann says that it cannot be too widely known that pain and foul-smelling discharge, both of which were formerly relied on as important diagnostic aids, are met with only in the later stages of the disease, frequently, indeed, when its extent is beyond any hope of eradication by surgical methods.

The book is well written, thoroughly up to date, and an able and authoritative presentation of what is yet known of this still most obscure subject.

The Treatment of Disease in Children. By S. A. Sutherland, M.D., F.R.C.P., Physician to Paddington Green Children's Hospital, to the Northwest London Hospital ,and to the City Orthopedic Hospital; Late President, Section for Diseases of Children, British Medical Association. Second impression. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, 1907.

The work under consideration deals with the diseases and ailments peculiar to children. Such general infections, usually considered as children's diseases, like the acute exanthemata are, however, not included. The arrangement of the book is the usual one, dealing at first with the feeding of infants and children in health and then passing on to the diseases of diet, rickets, and scurvy. Following these separate chapters are accorded the alimentary tract, respiratory system, cardiovascular, nervous, and genito-urinary systems. The concluding parts deal with Syphilis, Tuberculosis and Rheumatism. A short pharmacopœia and index complete the volume.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 31, 1908.

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

Address of the Retiring President.—Dr. WALTER LESTER CARR, after thanking the officers and the members of the various committees for the loyal co-operation and their support, said that as the Society had a membership of over twenty-one hundred, its business could not always be conducted in open meeting without unnecessary publicity and a belittling of the important objects for which it was formed. He was thankful that the two special meetings had upheld the authority of the Comitia Minora. The paid membership at the end of 1907 was 2,134, a gain of 34 for the year. Calculating this as a regular growth, the Society should have in a few years a membership of over 2,500 without special canvassing or coalition with other medical bodies. All reputable medical men in this county should be members. The greatest effort during the past year had been in the passage of the medical practice bill, now a law, and in opposition to the optometry bill. This latter bill was vetoed by the Governor after it had passed both houses. The imprisonment of a woman who conducted a house where abortions were habitually performed for maintaining a public nuisance had given the law officers of this Society a most important judicial ruling, as the precedent established should make it almost impossible for professional abortionists to continue their death-dealing trade. They had had a favorable decision in the Woodbury case, when the Court decided that a corporation could not practise medicine nor advertise. One of the many important sections of the new medical law prevented the advertising quack from hiding himself behind the name of an institution.

Address of the President-Elect.—Dr. J. RIDDLE GOFFE, in his address, said that the results of the amalgamation of the State organizations and the county societies and associations showed that personal animosities had vanished like dew before the morning sun; that no Achilles had skulked in his tent and no combination along old lines of cleavage had shown its head as a stumbling block in the way. He was not unmindful of the great honor they had conferred upon him, and he accepted it not only with grateful heart, but with a full appreciation of the obligation of service the position imposed. He knew they had a splendid system of organization, the machinery of which responded to the requirements of their home Society and also found a ready instrument for defensive or aggressive action at Albany. By means of the medical directory and the State journal the organization had been made compact. Organization in their ranks was the demand of the hour. "To cease to fear our fellows and learn to depend upon them, to do away with competition and build up co-operation is our one necessity." This he felt the members were learning more and more every day and putting into practice. Their percentage of membership, based on the whole number of practising physicians in the county was far below that of most of the counties. Those who were worthy should become members both to benefit the Society and to be benefited by it. The greatest good to the greatest number was the shibboleth of the Society. He had taken the responsibility of appointing a special committee, whose duty would be to select and solicit new members. With the cordial co-operation of each and every member of the Society he felt confident that the year 1908 would mark time with the most advanced progress of thought and endeavor and be reckoned with the successful years of this time-honored body.

The Life and Times of the Great Medical Reformer, Thomas Wakley, M.D., Founder of the London "Lancet."—Dr. J. RIDDLE GOFFE gave a very interesting address on the life of this man and of the times in which he worked.

The balance of the evening was devoted to a symposium on the recent epidemic of grippe.

The Scourge as It Appeared in Pittsburg.—Dr. JOHN A. LICHTY of Pittsburg presented this paper, which was read by the Secretary. He said that the epidemic of influenza which was at present prevailing in the city of Pittsburg began at the end of the second week of December and was, at the time the paper was written (January 20), slowly subsiding. Only occasionally new cases were now reported. The epidemic was widespread, though probably not so severe as in the noted pandemics of 1889 and 1890. Whole families, including servants and all associated with the household, were afflicted in rapid succession. The onset was sudden and severe, the usual symptoms of "pain all over" being most pronounced. The temperature did not usually go high, nor did it seem to be in accord with the severity of the symptoms when the patient took to his bed. In typical cases, where proper treatment was promptly established, the attack was unusually short, lasting from two, three, or four days. When treatment was neglected the symptoms dragged through one or two weeks. With proper care very few cases had any complications, and most of them were up in a few days with the usual languor and stiffness. Peculiar to this epidemic seemed to be the general complaint of sore throat. Upon examination the throat rarely showed other evidence of an abnormal condition than a rather dark cyanotic blush, which was most intense over the tonsils and faded out over the roof of the mouth. This was rarely associated with any swelling or edema. Another peculiarity which seemed to mark this epidemic was the frequency of involvement of that portion of the nasal cavity which was immediately between the eyes. The pain here was usually intense, and it seemed that many of the complications were due to the inflammation of this portion of the nasal mucous membrane. The complications most frequent seemed to be due to an extension from the nasal cavity into the frontal sinus, into the ethmoidal cells, into the antrum, and through the Eustachian tube into the middle ear. Otitis media and, in neglected cases, mastoid disease, were not infrequent. Such complications as pneumonia, nephritis, and gastrointestinal disturbances were not markedly prevalent; especially was this true of the last. The present epidemic was too recent to enable one to give an opinion upon the frequency or non-frequency of complications of the nervous system. As usual, chronic invalids and such as were suffering from nephritis, diabetes, valvular heart disease or certain pulmonary diseases very quickly fell victims and usually succumbed. For a time, and early in the epidemic, those physicians who were frequently exposed to the disease fell victims. Every evidence was present to show that the disease was highly contagious.

The Grippe in Baltimore.—Dr. G. HAMPSON JONES, Assistant Commissioner of Health of Baltimore, presented this paper, which was read by the Secretary. The Board of Health has not officially obtained much definite information regarding the amount or the character of the grippe pure and simple as it had existed in Baltimore. He, therefore, must give only that which he had obtained in his own practice and through conversations held with physicians of large practice and good power of observation. The grippe this year had not been violent in the symptoms produced, but their death rate had been considerably increased by the complications or sequelæ of grippe, principally pneumonia. The first manifestations of the grippe were headache, backache, limbache, with a slight elevation of temperature, seldom more than 102°; catarrhal symptoms developed secondarily and were not so prominent a feature as in former epidemics, when the attack was usually

ushered in "by cold in the head and coughing." He had found that the secondary catarrhal or respiratory tract affections were characterized more by an irritating cough than by the amount of discharge; or, in other words, the cough was due more to irritation of the terminal nerves than to the accumulation of mucus. Some few patients manifested gastric disturbances prominently, so much so that in one case the gastric symptoms were almost all that the patient complained about. These gastric symptoms consisted of vomiting, which came on suddenly and unexpectedly several times during the day, which was almost lik that of the vomiting of seasickness. The patient would feel perfectly well when nausea would suddenly develop and be almost immediately relieved by vomiting. The patient felt well then until the next attack, which would be in a few hours. One particular case was in a patient who did not suffer with gastric disturbances as a rule, and who got well in three or four days after the first attack. He found that patients could be partially relieved by proper treatment, but that the attack was seldom over in less than two weeks. He regretted that he could not give exact statistics, but, unfortunately, these cases were not reported except in death certificates. He was sure of the statement that the infection had been more extensive than at any period since 1895.

The Course of Grippe in New York.—Dr. Thomas Darlington presented this communication. He said this was the severest epidemic since 1901. The deaths from this cause had jumped from 9 to 42 and the record reached its culmination in December last, when 68 deaths were recorded. and then there was a gradual diminution in the number until 43 deaths from this cause were recorded for the week just past. The deaths reported as being attributable to this cause did not represent the real harvest. Its periodicity was shown in the early spring or winter. The greatest number of cases occurred between the ages of 25 and 85, and the greatest number of deaths at 65 years of age and over. Atmospheric influence was not a factor.

The General Features and Peculiar Manifestations.—Dr. Alexander Lambert said that this was of all diseases characterized by the intense degree of depression of both the nervous and mental system in proportion to the physical manifestations of the disease. There was an intense exhaustion and depression which came on even with what was apparently a mild attack. Thus it would prove a dangerous factor in cases of chronic tuberculosis, cardiac diseases, etc. Grippe was divided into the general pulmonary group and the intestinal group. In the one they saw cases of high temperature, with break bone symptoms, with or without delirium. This year the pain and neuralgic symptoms were marked. The pulmonary group were very prone to bronchitis. It was like a form of bronchorrhea. In the present epidemic the intestinal group predominated. The symptoms were more severe since 1891, but they were of rather shorter duration and presented a protean picture, not so marked.

The Grip in Children.—Dr. Charles Gilmore Kerley said there was no doubt but that the presence, or better, the effects of the grippe bacillus upon different structures, made them particularly susceptible to other microorganisms, such as the pneumococcus and the streptococcus. In the treatment of an uncomplicated case the child should be put to bed, given a laxative, and a reduced diet ordered. For children under three years of age one-half to one drop of tincture of aconite with two to five drops of spirits of nitre was given at two-hour intervals. For older children one grain of phenacetine in combination with two to three grains of salicylate of soda or aspirin was given at two-hour intervals when awake. In grippe rhinitis, a combination of camphor, belladonna, Dover's powder, and aspirin was usually given. The local treatment should be of a non-irritating character. If the angina was particularly severe, a spray of peroxide of hydrogen, one-fourth strength, was used. In cases of cervical adenitis, cold compresses should be kept on. The persistent tracheal cough was best controlled by sedatives. A combination of bromide and antipyrin or codeine or Dover's powder was given in sufficient doses to control the cough in a measure. If there was a bronchitis involving the smaller tubes, sedatives should be given sparingly. In grippe bronchitis he thought he got better results when he used creosote. In cases of tracheitis he used inhalations of moist air. Pneumonia in children with grippe was usually of the bronchial type, but presented no unusual requirements as to management. The digestive disturbances differed but little from those occurring in other infectious diseases. Inspection of the ear should be practised daily. Aurists and pediatricians frequently saw cases of middle-ear disease with mastoid, sinus or bulb involvement in which the aural inspection had been neglected, usually because of the absence of pain on pressure. One of the peculiar features of the present epidemic had been the insidious onset, the apparent prodromal stage with lassitude and temperature from 100° to 101° F. for two, three, or four days, when suddenly the process would become active with high temperature, prostration, and the complications. After grippe a tonic was generally indicated.

Some Throat and Sinus Complications.—Dr. C. G. Coakley said that the pathological changes in the mucous membrane of the pharynx, larynx, and trachea were not so severe as those occurring in similar epidemics of former years. Notwithstanding this fact, the inflammation and symptoms therefrom had persisted much longer than the pathological changes would seem to warrant. This could only be accounted for by the extreme bodily depression and lack of recuperative power. The most troublesome symptom in relation to the throat was a spasmodic, irritable cough, accompanied by only a small amount of glairy mucoid expectoration. In the pharynx there was the usual tendency to hypertrophy of the lymphoid tissue on the posterior wall behind the pillars of the fauces. In the larynx the most marked change had been a hyperemia and swelling of the inner ends of the aryepiglottic folds. The mucous membrane of the trachea had been but moderately inflamed, and in many cases the vocal cords were scarcely at all involved. As a large part of the cough was the result of the excessive irritability of the nerve endings in the inflamed mucous membrane of the pharynx and larynx produced by the frequent trauma of the paroxysms of cough, the most satisfactory treatment was found to be the administration of sedatives to reduce to a minimum the useless portion of the cough. Codeine, morphine, and heroin were the most valuable drugs for this purpose, but each had its objectionable features. Inhalation of sprays containing menthol in an oily vehicle had given temporary relief, but required to be repeated every two or three hours. He wished to emphasize the importance of the general practitioner differentiating between true neuralgias and the so-called neuralgia accompanied diseases of the accessory sinuses. The pain from sinus disease was often mitigated or absent at night, returning in the morning soon after rising and lasting with varying intensity until the middle of the afternoon, when it frequently disappeared. The headache might be bilateral when the sinuses on each side were involved, or unilateral when only one side was implicated. The point at which the greatest pain was described was not necessarily an indication of the sinus that was involved. Pressure over the anterior surface of the antrum, just below the inner canthus, was observed in many cases of antral disease. Pain on pressure on the under surface of the frontal bone, just above the inner canthus and internal to the supraorbital notch, was usually indicative of involvement of the frontal sinus. Deep-seated pain at the back of the orbit which was intensified on moderate use of the eye, and sometimes accompanied by indistinctness of vision,

often accompanied involvement of the posterior group of ethmoidal cells and the sphenoidal sinuses. If the practitioner would investigate the nasal cavities of all patients suffering from neuralgia, and having considerable mucopurulent discharge from the nasal cavities, either anteriorly or posteriorly, he was sure that he would be surprised to find the number of times these accessory cavities were filled with retained secretion. The treatment of the milder cases of sinus disease consisted in keeping the mucous membrane of the nasal cavities contracted so far as was possible with a 1-10,000 solution of adrenalin and, if necessary, judicious spraying of the nose with a 1 per cent. solution of cocaine by the physician or trained nurse. If the discharge was not greatly diminished in the course of a few days and the neuralgia persisted, then the nose should be thoroughly investigated, obstructions to drainage removed, and the cavities themselves irrigated with normal saline solution.

The Ear Complications.—Dr. Edward B. Dench said that an acute otitis media, complicating grippe, was usually characterized by the sudden onset and the severity of the pain. In some cases, especially in children, this pain was not so characteristic. The temperature often rose to 104 or 105° at the beginning of an attack, and remained high until the local condition was relieved by free drainage. A few winters ago extension of the middle-ear inflammation to the mastoid seemed to be the rule; in the epidemic of this year it occurred in but a limited number of cases. When the tympanic effusion was evacuated by free incision in the drum membrane within the first twenty-four hours of the onset, mastoid complications seldom occurred. In most of the cases of acute otitis complicating grippe, the mastoid tenderness developed exceedingly early, particularly tip tenderness. This tenderness usually passed away at the end of two or three days after the drum membrane had been freely incised. It was unwise to wait until there was a large amount of effusion in the tympanic cavity before performing this little operation of incising the drum membrane. The sooner the membrane was incised, the more rapid would be the recovery, while extension to the mastoid would be almost certainly prevented. After incision he used frequent irrigation of the external auditory canal with a solution of bichloride of mercury, 1-10,000, every two hours during the day and four hours during the night, while the discharge was profuse. The intervals were gradually prolonged as the discharge diminished. Between irrigations the canal should be kept lightly occluded with a pledget of cotton to prevent infection of the discharge in the canal. When the temperature in infants and young children in cases of grippe could not be explained, examine the ears, and in many cases an acute otitis would be found, although the child gave no evidence of pain in the ear. When the aural inflammation had extended to the mastoid, it was wise to operate very early. When once invaded the expectant treatment was absolutely useless. Operate at once; open the mastoid and thoroughly ablate the pneumatic structure and so avoid serious intracranial complications. In severe cases of grippe otitis, he believed that the mastoid and middle-ear involvement was simultaneous in many cases. If the temperature did not fall after incision of the drum membrane, if no visceral lesions were present, and if the temperature still remained high, the surgeon was warranted in opening the mastoid.

Resolutions.—The following resolutions were offered and passed:

Resolved, by the Medical Society of the County of New York: We desire to go on record as opposing Assembly Bill No. 268, being an act to amend the medical law of this State for these reasons: The Legislature at its last session enacted a law which placed a common requirement on all who desired to practise medicine in this State. This law grants exemption to all osteopaths who were practising in this State at the time of its passage, who were qualified according to osteopathic standards. The bill in question seeks to throw open the gates to all other osteopathic graduates, regardless of their qualifications. Also, that it is an unjust discrimination against graduates of medical colleges in this and other States who have to pass the Regents' examination before receiving the license to practise in this State. We believe this bill to be a type of class legislation directly contrary to the spirit of the constitution of the State.

Resolved, That the Committee be authorized to co-operate with the State Committee on Legislation in forwarding a copy of these resolutions to the proper authorities.

Respectfully submitted. Dr. E. Eliot Harris, Chairman, Committee on Legislation.

The following resolution was also offered, seconded, and passed:

That it is the unanimous opinion of the members of this Society that the unrestricted performance by qualified men of scientific experiments upon animals is essential to the maintenance and progress of the Science and Art of Medicine, and that the present laws of this State relating to this subject have proved adequate and satisfactory.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held on January 20, 1908.

The President, Dr. Thomas E. Satterthwaite in the Chair.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Robert T. Morris; *Corresponding and Statistical Secretary*, Dr. Frank C. Raynor of Brooklyn; *Treasurer*, Dr. A. Ernest Gallant; *Chairman for the Borough of Brooklyn*, Dr. J. Scott Wood.

Ureteral Catheterization.—Dr. F. Tilden Brown, after expressing his gratification over the increasing appreciation shown by the profession at large for the accurate diagnosis of urinary disorders and abnormalities, which was afforded only by this differentiating practice, proceeded to give a demonstration of his combined cystoscopic and radiographic table, as well as one connected with the development of the cystoscope since Nitze and Leiter first made their presentation in 1879. The speaker said that since 1894, when, after a successful and comparatively easy application of the unappreciated Brenner catheter cystoscope in a case of urinary tract tuberculosis, where the result served to decide an all-important question as to surgical interference, he became interested in testing the relative merits of the different catheterizing instruments existing at that period, and he was satisfied that for this purpose, in general, the direct-vision cystoscope was possessed of more advantage and fewer disadvantages than was the prismatic or indirect type. Hence his adoption of the Brenner pattern for his first efforts in the development of the cystoscope. Dr. Brown's remarks were directed more particularly to instruments and methods with which he himself had to do, and were supplemented by wall drawings and photographs to demonstrate the various developmental forms since 1900 of his original "composite cystoscope," which he claimed had been copied by a cystoscopist in another city. This composite cystoscope was a vastly more useful instrument than was its immediate predecessor, the author's double catheter direct-vision cystoscope, which was the first telescopic cystoscope, of any form, to provide for two catheters and effect synchronous catheterization of the ureters. But this instrument had no reserve channels for irrigation. It was with the end in view of finding a way to add such irrigation channels to the already practicable double catheter direct-vision cystoscope, while, at the same time, not increasing the circumference of the shaft beyond No. 24 French, that the Brown-Wappler efforts were first directed, in 1900.

with what initial success and constantly added improvements the present presentation was intended to demonstrate. It should here be added, the speaker said, that his first double-catheter instrument was but a modification of the then existing Brenner single cystoscope, whereas his subsequent instruments involved a wholly novel departure from all the pre-existing types. The first essential change lay in getting rid of the old-time terminal window at the vesical end of the sheath, followed, then, by the use of different kinds of interchangeable telescopic tubes for the same common sheath. Up to the present time its development on this basis had resulted in giving three complete cystoscopes for different purposes adjustable to one sheath. Still another tube to go with this common sheath was all but completed, in the shape of an indirect-vision double-catheter telescope. As to the uses of ureteral catheterization, Dr. Brown said these might come under two heads, diagnostic and therapeutic. The latter, in his belief, were quite limited, and he differed from those enthusiasts over kidney lavage of a few years ago, who, missing the diagnostic resources of this procedure, claimed to meet with so vast a number of patients with pyelitis as to astonish others who had long been studying such conditions. Not only had they discovered that pyelitis was very common, but, furthermore, that it was a leading factor in the causation of Bright's disease. From such original deductions regarding both the prevalence of pyelitis and their new etiology of Bright's disease, it was not difficult to foresee what a marked change the future mortality statistics in connection with such forms of renal disease, when treated by their medicated lavage of the pelvis, would show. The speaker said that he could appreciate the fact that there were exceptional cases of pyelitis which would be advantageously treated, at least in part, by this method, but that for the great majority internal medication, together with climate, hygiene, and diet, would be much more efficient and vastly safer. The therapeutic use of the ureter catheter, on the other hand, in cases of stones lodged in the ureter, was, from the speaker's experience, one of considerable importance. In not a few, the descent of such calculi had been determined at once or in intermitting stages, connected with each such stretching introduction of the catheter. Besides this mechanical effect of the catheter, it was of undoubted use in such cases when the eye of the catheter had reached a point above the lodged calculus, to employ either warm oil or add to the existing urinary hydrostatis pressure by the guarded and gradual injection of warm boric acid or saline solution. The efficacy of the ureteral catheter for the immediate relief of some cases of acute hydronephrosis, by carefully insinuating the eye of the catheter past the mechanical barrier, whether this was stricture of the ureter, angular bending of the ureter, or impaction of calculus, was self-evident. Where, in such cases, the catheter was successfully used, it was at once appreciated as being a therapeutic and diagnostic resource of the greatest value. The last therapeutic purpose of the ureter catheter which occurred to the speaker was that of serving as a tubular splint for a partly or completely severed ureter, whether such was the result of accident in abdomino-pelvic surgery, or any compression trauma of this tube incidental to accidents. Not only would extravasation be prevented by draining the urine past such laceration, but the presence of the catheter also served as a mandrel during suture of the ureter. The second, or diagnostic, uses of the ureteral catheter were vastly too numerous and well recognized to require comment. The speaker said he would dwell for a moment only upon the combined use of radiography with ureter catheterization. It was well known that many plates of the bony pelvis revealed shadows and that from the standpoint of shape and position it was impossible for even the most expert interpreters of *x*-ray plates to say whether these shadows represented a calculi in the ureter or some simulating body in the immediate vicinity. When these shadows were found in patients giving a fairly typical clinical history of lodged ureteral stone, the only nearly absolute safeguard for the surgeon, as well as patient, against an unnecessary operation, was to be had from the practice of first passing a ureter catheter to a distance beyond the site of this previously recognized questionable shadow, and then inserting a metal stylet (preferably of platinum) into the catheter, and again making an *x*-ray picture of both. Of course, when the questionable former shadow was seen in the same anteroposterior plane as the shadow of the metal stylet, in other words, when these were apparently in direct contact the diagnosis was very materially strengthened, while, on the contrary, it was almost completely dispelled if an appreciable space existed between the two shadows. A double ureter, encysted calculus, or something equally rare, would need to be involved in order to lead to error in diagnosis. It was because of the great value of this diagnostic resource that the speaker had made a table on which this entire procedure could not only be carried out in the specialist's office, but where no essential change or movement of the patient's body was necessary after insertion of the styletted catheter.

The Newer Methods of Examining the Bladder.—Dr. Frederick Bierhoff said the methods of examination of the bladder which were at our disposal were: Inspection, palpation, exploration with the sound, exploration with the catheter, digital exploration, exploratory incision, examination by the *x*-ray and examination by direct illumination. Of the above enumerated methods, all, with the exception of examination by the *x*-ray and by direct illumination had been in use for many years and gave comparatively little and usually unsatisfactory information concerning diseases of the bladder. The last two methods were the more modern developments in the line of bladder examination, and of these examination by direct illumination by means of the cystoscope was the most exact and satisfying. Each of the methods enumerated gave us some information. All, however, with the exception of cystoscopy and exploratory incision, were uncertain and unsatisfactory, while the latter was a procedure of so grave a nature that it should only be employed when all other methods failed. The certain method of examination of the bladder was and must remain the method of direct illumination by means of the cystoscope, for no other method gave us so much information as this. Where any stiff instrument could be passed at all into the bladder, the cystoscope might be employed. The speaker said he had examined with it children as young as four years, and he felt confident that were the need to arise he would be able to examine even younger children with it. While cystoscopy was not free from dangers, particularly in the hands of inexperienced or careless operators, it offered, when properly and carefully employed, the minimum of danger and the maximum of utility. There were two methods of examination—or, rather two types of instruments—those for direct vision and those for indirect. The instruments of the direct-vision type were all modifications of the principle first laid down by Bozzini, who, in 1806, first proposed a method of examining the various canals of the body by means of his so-called "light-carrier." Of the instruments in use at the present day which were representative of the direct method, those of Pawlik-Kelly and Brenner, with their modifications, were the representatives. The indirect method was that of Nitze, and the instruments employed were all modifications of Nitze's original prismatic cystoscope. While the straight telescopic instruments had the advantage that they did not invert the image, they suffered from the disadvantage that there were parts of the bladder interior which could not be seen when such instruments were used. By means of the prismatic cystoscope, however, every part of the bladder wall might be brought into the field of vision, and to the experienced

cystoscopist the inversion of the image formed no obstacle whatever to correct examination and interpretation. Recently, Jacoby of Berlin had devised an attachment by means of which the inverted image might be restored to the original position. In order to successfully cystoscope a patient, whether male or female, the operator must understand the construction of his instrument and the accidents to which it was subject; the urethra of the patient to be examined must allow of the easy passage of the instrument. For the examination of children, an especially small cystoscope, made particularly for that purpose, should be employed. The bladder should be capable of a sufficient degree of distention to make free excursion of the beak of the instrument possible. The bladder must be filled with a transparent medium, and to that end must be irrigated until the fluid used to cleanse it returned perfectly clear. Any bland, non-irritating fluid which was perfectly transparent, such as sterilized water or sterilized normal saline solution, or boric acid solution, might be employed. Air had also been used to fill the bladder and its supporters. Most cystoscopists, however, preferred a fluid medium. The light should be sufficiently powerful to illuminate clearly the bladder wall. In conclusion, the speaker stated that the prismatic type of cystoscope, as originally presented by Nitze, in 1879, was and would remain the instrument par excellence for the satisfactory examination of the bladder.

Notes on Over-Treatment of the Urethra and Bladder.—Dr. James Pedersen, under this title, reported three cases of urethral trouble, which illustrated the injurious effects of over-treatment. One case was that of a young man who had a slight urethral discharge for which he consulted his physician, who promptly pronounced it "no infection" and passed a full-sized urethral sound. This gave the patient pain and produced some bleeding. The next day he had a chill, followed by a high temperature, together with increasing frequency of urination and progressive obstruction. These symptoms became so marked by the following week that the patient took to his bed. A few days later (twenty days after the instrumentation), complete retention occurred, and for one week he was catheterized daily without any change in his condition. At this time, when Dr. Pedersen first saw him, a soft catheter was introduced without difficulty, and twenty-four ounces of chocolate-colored urine were withdrawn from the over-distended bladder. Catheterization every eight hours was then carried out, to prevent a recurrence of the over-distention. Two days later fluctuation in the prostate appeared. Pus was evacuated through a median vertical perineal incision, and the patient made a rapid recovery. After a safe interval (eight days) treatment of the cystitis and dilatation of the stricture was begun.

Conservative Prostatectomy.—Dr. Follen Cabot said that during the past few years much progress had been made in the treatment of prostatic hypertrophy. The advancement had been mainly along surgical lines. The mortality of 18 to 25 per cent. of ten years ago had been gradually reduced until now it averaged about 7 per cent. The results of the operation as to the urinary function, etc., had also shown much improvement. The speaker said that in his own series of seventy-two complete prostatectomies performed in the past five years he had lost five patients. Two of these were diabetics, and the others were worn out from long suffering. In looking back over these deaths he believed that with his present experience and change in methods he could have saved at least three of those men. The speaker divided prostatics into three groups. In the first group he placed the cases which were beginning to show evidences of prostatic obstruction. In the second group he placed those cases which had two or more ounces of residual urine, who were straining considerably, and getting up four or five times at night to empty the bladder. In the third group he placed those prostatics who could no longer be treated by palliative measures, they were usually very much shattered in health and could not withstand much surgical shock. The catheter no longer gave them relief, but often was the cause of hemorrhage, chills and pain. A man's age, Dr. Cabot said, really had little to do with his power to resist operative shock. The circulatory apparatus, kidneys, and general condition must, however, be carefully studied in every instance. In the first group of prostatics, those in good health and with mild symptoms, no operation was advisable unless there was evidence of advance in the obstruction. In the second group we usually had evidence of cystitis and often a secondary pyelitis. The catheter had to be used occasionally or perhaps constantly to keep the patient at all comfortable. The broken rest, the use of the catheter and all it entailed really made him an invalid, and there was always danger of infection and other complications which suddenly brought the patient into the third group. In this third group something of a surgical nature was necessary in order to preserve life, and often there could be no further delay. The question therefore arose in all cases in this group, and some of those in the second one, what shall we advise? A complete prostatectomy was almost sure to be followed by death. Dr. Howard Lilienthal had answered this question in 1896 by suggesting and carrying into practice a two-stage operation. Dr. Cabot said he had followed this plan several times and believed it to be of the greatest value. In all cases where he had the least doubt of the patient's resistive power, he now did the two-stage operation. The patient in a state of shock or low resistive power was quickly prepared for operation, and a suprapubic cystotomy was done under local or general anesthesia. This should not take more than five to eight minutes, and by this measure we obtained all the advantages of a complete operation without its disadvantages. The patient was put to bed wearing a good-sized drainage tube; he was made to sit up at the end of twenty-four or forty-eight hours and drained in this way till his condition was so good that a prostatectomy could be quickly performed through the same cut. The patient might sometimes wear the tube indefinitely. The cystitis gradually disappeared, the kidney condition improved, the engorgement of the prostate passed off, and the patient, through rest and forced feeding, regained his lost strength. He then was given a small amount of chloroform and the prostate enucleated in a few minutes. The suprapubic route was the best one for this two-stage operation, owing to the comfortable position of the tube.

Dr. Parker Syms said Dr. Brown's work in connection with the evolution of the cystoscope deserved much praise. His own experience with ureteral catheterization was very slight. He recognized the fact that in a certain limited number of cases it was a procedure of much value, and that in the hands of most skilled and careful operators it might be sufficiently devoid of danger to make its employment justifiable. On the other hand, he wished to sound a note of warning against its indiscriminate employment, and he believed that catheterization of the ureters should be limited to those cases wherein a diagnosis was absolutely necessary and wherein other means had failed. What the speaker referred to was the grave danger of infecting a healthy kidney by ureteral catheterization, and while he would not insist that the method should be discarded, he wished again to emphasize the fact that its employment should be limited to the most skilled experts. In discussing Dr. Bierhoff's paper on the newer methods of examining the bladder, Dr. Syms said our former methods of exploring the bladder—excepting exploratory incision—had left us with very inadequate means of knowing the conditions of that organ, and for that reason the cystoscope had proved a very important instrument; but here, too, he wished to give a warning as to dangers and

limitations. No matter by whom the cystoscope was employed, the findings were not always comprehensive. Positive proof might be of value, but negative proof was not always conclusive. In certain conditions of the bladder the employment of the cystoscope was attended with serious danger. In speaking of prostatectomy he said that the divergent opinion that had formerly prevailed among surgeons as to the propriety of operating under certain conditions were now more or less harmonized, although the best method and manner of approach were still a fruitful source of discussion, and both the upper and the perineal routes had warm advocates. Personally he had always felt that the perineal operation was the one of choice, and statistics proved that the mortality by that route was much less than by the suprapubic. In speaking of the mortality of this operation, we should have in mind not only that due to the immediate operation, but also that occurring during the convalescence. One great advantage of the perineal operation was the short time required for its performance, and the brief confinement of the patient to bed. His patients were usually up within forty-eight hours. As to performing the operation in two stages, Dr. Syms first resorted to this expedient over ten years ago, and had always employed it in cases of very feeble men, and in several instances it was the only way in which the patients could have been safely operated upon.

Dr. George Magan Muren of Brooklyn thought the cystoscope was employed entirely too frequently and that other useful means of diagnosis had been neglected by those who were enthusiastic cystoscopists. The patient's welfare was thus jeopardized by the too frequent use of this very valuable instrument. In discussing prostatectomy, Dr. Muren said that frequent reference had been made to selected cases, but nobody had said anything about the unselected cases, the old men whose general condition was such that any operation would in all probability prove fatal. He had seen them die after the suprapubic operation and after the perineal, and also after the two-stage operation described by Dr. Cabot. The speaker said that in dealing with this class of cases he preferred permanent suprapubic drainage, and for that purpose he showed an apparatus which he had found very serviceable in draining the bladder, with a stop-cock attachment to prevent leakage.

Dr. Martin W. Ware said that both Dr. Brown and Dr. Bierhoff had made it clear that the cystoscope was an instrument of precision, and it was perhaps not going too far to claim that it could be placed on a par with the microscope. In coming to a conclusion, we rarely relied solely on the microscopic findings, to the exclusion of other factors, and we should look upon the cystoscope in the same way. A proper cystoscopic examination always required time and deliberation, and it should never be regarded as a procedure of exigency. The speaker, after referring to the valuable work done by Dr. Brown in connection with the improvement in ureteral cystoscopy, said there were certain cases where the conditions were such that direct illumination of the ureteral orifices was impossible and which called for the use of the Nitze instrument. While the possibility of infecting a healthy kidney by ureteral catheterization should be borne in mind, the proofs of that fact were lacking, particularly in tuberculous conditions, and personally the speaker said he was inclined to believe that the danger of infecting the opposite organ by this method was largely a myth. Cystoscopy in children, to which Dr. Bierhoff had referred, was a field that was not yet thoroughly open to us. In children under five years of age the caliber of the urethra was so small that the instruments thus far devised for the purpose of exploring the bladder had not proven satisfactory on account of the small size of the prism that had to be used. As a possible satisfactory substitute, the speaker suggested the use of the salpingoscope, with a properly lengthened shaft. This instrument, as now made, was of the Nitze type and was employed by rhinologists in examining the orifices of the Eustachian tubes.

Dr. F. Tilden Brown, in closing, said that while he believed that the vast majority of patients requiring ureteral catheterization could be reached with the direct instrument, and while that method was, from his point of view, somewhat preferable to the indirect for a variety of reasons, among them being that it required less time and there was less tendency to leakage, he fully appreciated the value of the prismatic ureteral cystoscope in somewhat atypical cases. Dr. Ware had admirably answered the criticisms of the other speakers with reference to the risks attending catheterization of the ureters, and the speaker said that in his personal experience he was not aware of any accident in the cases he had examined. He had repeatedly convinced himself that the instrument and all its appliances could be thoroughly sterilized by subjecting them to formaldehyde vapor, and this measure, together with proper cleansing of the urethra and bladder, and performing the operation under strict aseptic conditions, removed wholly any danger of infection. Even if the tip of the instrument, after accidental infection, was introduced into a healthy ureter, and no trauma was produced, he doubted whether an ascending infection with ultimate involvement of the kidney would occur. The infections of the kidney were usually of hematogenous origin, and the possible danger of an ascending infection was regarded as less likely than formerly except from the gonococcus and colon bacillus.

Dr. Bierhoff, in closing, said he had been perfectly satisfied with his results with the indirect-vision cystoscope. He did not agree with Dr. Muren that the cystoscope was used too frequently and to the neglect of other and better methods of diagnosis. In doubtful cases he did not think it was just either to the patients or to ourselves to tinker with unsafe or unsatisfactory methods instead of at once resorting to the cystoscope, which was the most complete and scientific method of examination, and which offered us the maximum of information at the minimum of risk. As Dr. Ware had said, it should be looked upon as an instrument of precision, but it certainly was an unsafe instrument in incompetent hands. Here, as in any other field of medicine, experience was necessary, and even the most experienced at times could not form a complete diagnosis upon the result of a single cystoscopic examination. In regard to cystoscopy in infants and children, Dr. Bierhoff said there were instruments on the market with a caliber as small as No. 14 F. and even No. 11 F., and with these a perfectly clear picture of the bladder could be obtained.

Dr. James Pedersen, in closing, said that he had seen a ureteral calculus pass after a ureteral catheter had been used, and also that he had seen a calculus dislodged from the ureteral orifice by passing a searcher over it. Referring to the use of the styletted ureteral catheter, he quoted a case recently reported by Dr. Forbes Hawkes in which a radiograph showed a shadow situated at some distance from the shadow of the stylet. Subsequent operation proved the shadow to be due to a calculus which had become lodged in the ureter. The case was explained as one of bifurcated ureter, the ureteral catheter having gone up one division, while the calculus lay in the other division. Regarding the possible danger attached to cystoscopy, he gave it as his opinion that under proper precautions and in skilled hands, cystoscopy, with or without catheterization of the ureters was as safe a procedure as, for example, the use of the urethral sound, which, carelessly used, was capable of doing harm. He spoke favorably of the two-step operation in certain cases of prostatectomy, and referred to an emergency case to which he had been called, in which he was convinced that preliminary drainage before the prostatectomy had been the means of saving the pa-

tient's life. He called attention to the fact that, whereas suprapubic drainage is well borne in, practically, every case, perineal drainage often has to be discontinued because of the intolerance of the inflamed prostatic urethra and prostate.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held November 19, 1907.

DR. GLENTWORTH R. BUTLER IN THE CHAIR.

The Construction of a Successful Medical Paper and Its Proper Discussion.—Dr. LE GRAND KERR of Brooklyn read this paper. He said that the word successful was elastic, the meaning being largely colored by the attitude, either ethical or material, which the individual took toward the study of medicine. A successful medical paper was one that was informing, suggestive, or reforming, or which combined two or more of these elements. An informing paper did not have to state new facts, but could place old things in a new light, or by iteration, give them new force. Such a paper was at once successful, although the degree of that success was determined by the fact whether the information was instructive to the few or the many. Reports of cases under personal observation furnished examples of such a paper. A suggestive paper was usually gleaned from experimental research or by the pursuance of laboratory methods, but not always so, for frequently clinical papers were read which simply stated facts, and through the modesty of the writer debarred him from drawing conclusions, yet such a paper could be very suggestive to the hearers. The highest type of a reforming paper was that which presented clearly defined means or methods by means of which the community and the individual could be lifted morally, mentally, as well as physically. The construction of a successful medical paper demanded that it be written clearly and accurately, that it be constructed without prejudice, and that it state an experience, either directly or by inference. There were other elements which added materially to the value of a paper, but which were not absolutely essential to its successful construction. They were: conciseness, a reasonable calculation of the importance or non-importance of the pathogenic, subjective, physiological, or basic principles, and the construction of a logical argument. Argumentation was not absolutely necessary to a successful scientific paper, and although greatly to be desired, accurate conclusions might not be necessary, for a paper which contained a real experience stated clearly and without prejudice had in it the essential elements of success, even though that experience added weight to already known facts. It was only necessary to look over the table of contents of any of the medical journals to be convinced that the titles were in many instances framed with scant carefulness. The title was to be so worded as to define as clearly as possible the subject to be discussed. In the construction of the text much consideration had to be given to the audience. A paper intended for men skilled in some special branch of medicine or surgery was not to be written in the same manner as one intended for the general practitioner. The treatment of the theme had to adapt itself to the environment. When terms were used in the text that had a doubtful or double meaning they had to be defined accurately. The use of English in place of Latin terms was desirable. The facts were to be stated clearly and briefly, but in no case was brevity to detract from accuracy. To be concise was good; to be accurate was better. It was helpful, particularly if the paper was to be printed, to conclude it with a clear-cut summary. Medical papers could be divided into three large classes, the experimental, the analytical, and the topical. The value of an experimental paper depended upon three things, accuracy of observation, a mind free from prejudice and open for impression, and the ability to report correctly. It was rare to find these three qualities combined in the same individual, and the result was that much experimental work was valueless, or nearly so, until the results of such work had been analyzed or reanalyzed by others than the original investigators. The value of an experiment depended on the individual performing it, as well as upon the materials, or animals experimented upon. When reasonable inductions had been formulated from laboratory experimentation they had to be proved in practice, so that the practitioner became the court of last resort. An analytical paper was almost always didactic in its purpose, and its value depended on its simplicity and orderly arrangement. The best analytical papers were written by men who were born teachers. All such papers fell short of their purpose if they failed to observe the laws of adaptation, cooperation, definiteness, system, and repetition. Topical papers were the most successful contributions to medicine because they came mainly from practitioners and appealed to the same class. They were valuable because they reported actual clinical experience; they were written without the bias which was frequently the result of close specialization; they added weight to already recognized truths; they were sometimes original, often suggestive, and were always welcome. There was a tendency among the profession in general, among specialists in particular, and among editors almost without exception, to discourage the reading of, or publication of, medical papers by unknown men. The inevitable result of this had been that "impractical papers" had been the rule rather than the exception. The race seemed to have been for singularity, and the prize too often self-aggrandizement. Originality had its place, and a very large one, in medicine, but that place was not to discourage the efforts of those men who were unable or too modest to claim it. In the construction of a topical paper, too much stress was not to be placed upon the opinions of authorities; they were to be quoted and recognition made of their opinions, but the real authority in any given case was the man directly in charge of that case, and the too ready acceptance of every opinion and statement made by an authority soon vitiated the influence of individual effort and reasoning. The proper discussion of a medical paper required that the opener assumed the right attitude toward the paper and its purpose. Discussion was not criticism, although criticism might at times play a rôle in the act of discussion, but when it did it was a minor part. There were two parties to the discussion of a paper—the opener, and by common courtesy, the author of the paper, who closed the discussion if he so wished. Many times the attitude of the former seemed to be the discovery of possible flaws in the make-up of the paper, criticism instead of appreciation of its points, and the final application of a verbal balm that was applied to soothe the injury that may have been done. The attitude of the second party of the discussion was often that of unqualified defence of his paper instead of that seeking after truth which should influence all of the physicians thinking fulsome approbation was too much used in the discussion of papers. The discussion was to be brief and pointed, and in every case pertinent to the paper. Brevity was not absolutely essential, if the speaker was concise and logical in his remarks. That man was not to be encouraged who prefaced his remarks with the statement, "I have nothing to add to the discussion, Mr. President," and then gave the audience a practical demonstration of a verbal diarrhea,

which was not amenable to treatment. To get the most out of a medical paper for the hearers was to get the most into it for the writer. Access to an abstract of the content of the paper before its reading or publication was much to be desired.

Opsonins and Bacterial Vaccine Therapy. (a) Theory and Literature.—Dr. GEORGE B. WHITE of Brooklyn read a paper with this title.

(b) The Technique (with Lantern Slides).—Dr. WILLIAM H. WOGLOM of Brooklyn presented this phase of the subject.

(c) The Practice and Therapeutic Value.—Dr. NATHANIEL BOWDITCH POTTER of New York read this paper.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

At a stated meeting, held February 6, Dr. JAMES M. ANDERS reported "A Case of Multiple Sacculated Thoracic Aneurysm Successfully Treated by Wiring," and he exhibited the patient, a mulatto, some thirty years old, with a syphilitic history. At the time of operation, more than a year previously, the skin and other tissues overlying the pulsatile tumor, near midsternum, had become so thinned as to give rise to fear of rupture. No. 26 silver wire was introduced through hollow needles and pulsation at once diminished. Subsequently the soft tissues actually sloughed away and a considerable amount of the wire was removed. *X*-ray examination showed the aneurysm had become much reduced in size. At the time of report, however, expansile pulsation had become manifest in another situation, although the man had been quite comfortable in the interval. Dr. JAMES P. MANN described the operation performed by him in Dr. Anders' case. Silver wire was selected because of its resistance to corrosion and its lesser liability to kink. Electrolysis was not employed because pulsation ceased as soon as the wire was introduced. Dr. G. E. PFAHLER exhibited negatives showing *x*-ray pictures of the aneurysm at successive periods. Dr. JOSEPH SAILER presented a communication entitled "Sacculated Aneurysm of the Arch of the Aorta Ruptured Into the Superior Vena Cava Without Symptoms of Venous Obstruction," and he exhibited the specimen. The case is unique in the fact that in all other recorded instances in which a similar condition was present there were observed cyanosis and edema of the upper portion of the chest, the neck, and the upper extremities. Dr. JOSEPH MCFARLAND presented a communication entitled "The Pathogenesis of Aneurysm of the Aorta," supplemented by an exhibition of specimens. He pointed out that the factors usually assigned for the development of aneurysm are increased pressure within the arterial system and a morbid state of the blood-vessels, but not rarely both of these conditions are present without the formation of aneurysm. The classification of aneurysm is difficult, the gradation from a simple dilatation to an unequivocal aneurysm being exceedingly delicate. Dr. HENRY K. PANCOAST read a paper entitled "The *X*-ray Diagnosis of Aneurysm of the Aorta." He held that while the results yielded by radiography in the diagnosis of aneurysm are most important they are not invariably conclusive and not infallibly correct. Dr. HOBART A. HARE presented a communication entitled "The Wiring Operation in the Treatment of Aneurysm of the Aorta, and the Influence of Drugs Before and After Operation." He had operated or assisted in operating on fifteen cases of aneurysm by the introduction of gold wire and the passage of a continuous galvanic current. He had been struck by the relief of pain and other oppressive symptoms and the reduction in the tumefaction immediately after the operation. In some cases life had been prolonged for three years, and the patients had been able to attend to important duties in the interval. Care must be taken to avoid the induction of electrolytic sloughing of the skin, as the wound thus caused fails to heal and is likely to lead to rupture of the aneurysm. Dr. Hare knew of no drug that was useful in the treatment of aneurysm, unless, perhaps, it was aconite that diminished the activity of the heart. Dr. W. S. NEWCOMET exhibited negatives illustrating the aneurysm in one of the cases discussed by Dr. Hare. In this instance interesting information was gained also by fluoroscopic study, with the aid of which the dilatation and collapse of the enlarged vessel could be seen.

SECTION ON GENERAL MEDICINE.

At a stated meeting, held January 13, Dr. B. FRANKLIN STAHL presented a patient with Adams-Stokes disease. The case occurred in a man about 54 years old, without a history of syphilis, who presented classic symptoms of heart-block, without convulsive seizures. The pulse at times fell as low as 13 in the minute. Dr. GEORGE W. NORRIS exhibited "pulse-tracings from the foregoing case, demonstrating the heart-block." By graphic methods it was shown that for every ventricular contraction there were three auricular contractions. Dr. JOSEPH ERLANGER of Madison, Wis., by invitation, read a paper entitled "Recent Advances in the Pathological Physiology of the Heart, with Especial Reference to Arrhythmia." He pointed out the various degrees of rhythmic contractility in different parts of the heart, and he dwelt on the transmission of motor impulses from one part to another part of the heart. These impulses were in general transmitted from the auricles to the ventricles, and they seemed to originate in the right auricle at the points of entrance of the great veins, in the vicinity of the venous sinus. Disorders of rhythm had been demonstrated experimentally and in some instances had also been shown clinically to be due to interference with or lesions of the conducting structures. Dr. LEWIS A. CONNER of New York, by invitation, read a paper entitled "The Clinical Study of Heart Disease." He indicated that too little attention was paid to the fundamental principles in the physical study of the heart, namely inspection, palpation, percussion, and that almost too much dependence was placed on the results of auscultation to the exclusion of the other methods of diagnosis. The results of *x*-ray examinations were somewhat disappointing, but more was to be hoped for from orthodiagraphy, by the aid of which the distortions occurring in radiograms are to be avoided. Dr. THEODORE C. JANEWAY of New York, by invitation, read a paper entitled "The Use and the Abuse of Digitalis and Other Heart Tonics." He pointed out the necessity in every case in which digitalis was prescribed of seeing that a good preparation was furnished. It was necessary that the leaves of the second year's growth not more than a year old be employed. The best preparations are a good infusion and a good tincture. The active principles or glucosides are not stable preparations and accordingly are not to be depended upon. The infusion must be freshly prepared and should never be made from a fluid extract. Two drams of a good infusion constitute an efficient dose. When the infusion is not borne by the stomach, the tincture may be employed hypodermatically or rectal administration may be resorted to. A poultice of digitalis leaves is too expensive a method of application, especially in proportion to the results. Digitalis is particularly indicated when there is unduly rapid action of the heart or arrhythmia in conjunction with want of tone of the left ventricle. In the discussion that followed, Dr. JOHN H. MUSSER spoke of "The Importance of Instruments of Precision in the Study of Heart Cases." He dwelt especially upon the importance of tracings of cardiac, arterial, and venous pulsation, and of blood-pressure in the interpretation of signs and symptoms of circulatory disorder. Dr. HOBART A. HARE took up for consideration

"Remedial Measures Other Than Drugs in the Treatment of Heart Disease." He spoke of the value of rest, of massage, of hydrotherapy, and of diet as valuable measures in the correction of circulatory derangement. Dr. ALFRED STENGEL spoke of "Extracirculatory Manifestations of Cardiac Failure." He dwelt upon certain reflex and other nervous phenomena resulting from disturbances in the circulation, as well as impairment of nutrition, which was sometimes observed. Dr. JOSEPH SAILER made some remarks on "Blood-Pressure in Relation to Prognosis in Heart Disease." He stated that the three gradations in pressure, namely low, normal, and high, gradually merged the one into the other, although an unfavorable prognosis might be made when the pressure became unduly high or unduly low. In general the high blood-pressure of vascular disease was of more serious prognostic significance than that of renal disease.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

REGULAR BOARD OF MEDICAL EXAMINERS, STATE OF GEORGIA.

Atlanta, October 8, 1907.

CHEMISTRY.

1. Give the chemical name of water, its formula, and its composition by weight and volume.
2. Give the chemical name of white arsenic. Give the names of three preparations of arsenic used in medicine. What salt of iron is an antidote for arsenic poisoning?
3. Give the chemical and pharmaceutical names and formulas of two compounds of mercury and chlorine commonly used in medicine.
4. Differentiate between chemical and physiological antidotes.
5. Give a good test for indican in the urine. What is the clinical significance of indican in the urine?

ANATOMY.

1. Give the divisions of the vertebral column. (a) Describe one vertebra under each division. (b) Describe typical rib.
2. Give anatomy of shoulder joint.
3. Bound triangles of the neck. Give contents of each. (Draw a diagram.) (a) Give origin and insertion of (1) Latissimus dorsi, (2) Pectoralis major, (3) Triceps, (4) Supinator longus.
4. Give anatomical relations of the liver.
5. Describe brachial plexus.

SURGERY.

1. Name the varieties of fracture. (a) State the cardinal principles in the treatment of fractures.
2. Give diagnosis of hydrocele and best method of operating for its cure.
3. What is intussusception? (a) Describe an operation for intestinal anastomosis.
4. State best method for radical cure of varicocele.
5. Describe an operation for the removal of the mammary gland.

MATERIA MEDICA AND THERAPEUTICS.

1. Name the most commonly prescribed coal tar derivatives and their therapeutic uses and dangers.
2. Source of opium. Name four of the most important preparations and their therapeutic uses.
3. Source of quinine, indications and contraindications for its uses.
4. Define escharotic and name one or more and their mode of action.
5. Write prescription for chronic malarial poisoning.

OBSTETRICS AND DISEASES OF CHILDREN.

1. What diseases in the mother are liable to injure the fetus *in utero?*
2. What structures compose the fully developed umbilical cord?
3. What are the causes of labor at full term?
4. What principal dangers may arise after delivery is completed, and how should we guard against them?
5. Cause and treatment of post-partum hemorrhage.

PHYSIOLOGY.

1. What is the difference between mucous membranes and serous membranes, anatomically and physiologically?
2. Define lymph, chyme, and chyle.
3. What is the normal pulmonary capacity in the adult? Name the subdivisions and the capacity of each subdivision.
4. Name the four parts which constitute the circulatory system, briefly giving their functions.
5. Mention the cranial nerves of special sense, giving function of each.

PATHOLOGY.

1. Describe the pathological changes in blood in pernicious anemia.
2. In what condition do you find the tissues surrounding an indolent ulcer?
3. (a) Name the obligate bacteria. (b) Differentiate between the changes produced by staphylococci and tubercle bacilli.
4. What are the pathological changes produced by cirrhosis of the liver?
5. Differentiate between carcinoma and sarcoma.

GYNECOLOGY.

1. What is amenorrhea? (a) State the causes and treatment.
2. What is Alexander's operation? (a) State indication for and manner of performing it.
3. Describe prolapsus urethræ; state what it might be mistaken for and the proper treatment of it.
4. Give symptoms and treatment of acute cystitis in the female.
5. Describe briefly the uterus, ovaries, and Fallopian tubes.

PRACTICE.

1. Give symptoms and treatment in bilious colic.
2. Differential diagnosis: Typhoid and malarial fever and treatment of each.
3. Symptoms and treatment in uremia.
4. Cause and symptoms in mercurial stomatitis.
5. Differential diagnosis in rheumatic fever and gonorrheal rheumatism.

OBSTETRICS.

1. Define puerperal eclampsia and give its treatment.
2. Give causes, symptoms, and management of a case of rupture of the uterus.
3. Give average capacity of a child's stomach at birth; three months; six months, and twelve months old.
4. Symptoms and differential diagnosis of varicella.
5. Differential diagnosis between broncho- and lobar pneumonia.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

REGULAR BOARD OF MEDICAL EXAMINERS, STATE OF GEORGIA,

Atlanta, October 8, 1907.

CHEMISTRY.

1. WATER. *Chemical name,* hydrogen monoxide. *Formula,* H_2O. *Composition by weight,* sixteen of oxygen and two of hydrogen. *Composition by volume,* one of oxygen and two of hydrogen.

2. The chemical name of white arsenic is arsenic trioxide. Three preparations of arsenic used in medicine: Liquor Potassii Arsenitis, Liquor Sodii Arsenatis, Liquor Arseni et Hydrargyri Iodidi.

Freshly prepared ferric hydroxide is the antidote for arsenic poisoning.

3.—

Chemical Name.	Pharmaceutical Name.	Formula
Mercurous Chloride	Hydrargyrum chloridum mite	Hg_2Cl_2
Mercuric Chloride	Hydrargyrum chloridum corrosivum	$HgCl_2$

4. *Chemical antidotes* act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound.

Physiological antidotes act as such by combating the physiological action of the poison.

5. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the

chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

Indicanuria is found in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation: also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc. (From Witthaus' *Essentials of Chemistry.*)

SURGERY.

1. Fractures are variously classified:

(a) Simple, compound, and complicated.

(b) Complete (transverse, oblique, spiral, longitudinal) and incomplete (fissured, greenstick).

(c) Single and multiple.

(d) Comminuted, impacted, etc.

(e) Intra- and extraarticular; intra- and extracapsular.

The cardinal principles in the treatment of fractures are: Reduction, coaptation, immobilization, and suitable measures for promoting the nutrition of the part and for preventing adhesions in the neighboring joints and muscles. Compound fractures, in addition, demand: Asepsis, removal of foreign matter or damaged tissues, stopping the hemorrhage, and measures to combat shock.

2. Hydrocele is diagnosed by its *translucency*. Further, it is a tumor which grows from below upward, is tense and fluctuating, is generally situated in front of the testicle, and gives no impulse on coughing.

Volkmann's and von Bergmann's operations are both recognized methods of treating hydrocele.

3. *Intussusception* is the prolapse of one part of the intestine into the part immediately below.

MATERIA MEDICA AND THERAPEUTICS.

1. The most commonly prescribed *coal tar derivatives* are: Acetanilid, phenacetin, antipyrin, phenol, cresol, salicylic acid, naphthol, guaiacol, salol, creasote, and sulphocarbolates.

Their *therapeutic uses are*: As antipyretics, as analgesics, as antiseptics, as narcotics, and as germicides; they also aid in the formation of hemoglobin.

Their *dangers* are: They are irritants, poisons; they produce collapse, shock, digestive disturbances, skin eruptions, cyanosis, chills, excessive sweating, depression of the central nervous system.

2. The *source of opium* is the exudation from the unripe capsule of the *Papaver somniferum*.

Four of its most important preparations: Morphine sulphate, tincture of opium, camphorated tincture of opium, powder of ipecac and opium.

Therapeutic uses: As an anodyne, a hemostatic, in inflammations, as an expectorant, in diarrhea, in alcoholism, manias and diabetes, as an antispasmodic, in insomnia, and as a diaphoretic.

3. Quinine is an alkaloid obtained from the bark of cinchona.

Indications: In malaria, neuralgias, hay fever, acute coryza, and as a stomachic tonic.

Contraindications: Inflammations of the middle ear, gastrointestinal tract, kidneys, or bladder; also where the patient has an idiosyncrasy.

4. *Escharotics* are agents which destroy the vitality of the tissues to which they are applied.

They may act: (1) By abstracting water from the tissues, as sulphuric acid, caustic potash. (2) By corrosive deoxidation of the tissues, as chromic acid, bromine. (3) By combining with the albumin of the tissues, as silver nitrate, zinc chloride. (4) By carbonizing the tissues, as the actual cautery and the moxa.

5. A prescription for chronic malarial poisoning:

℞ Quininæ sulphatis, ℥j.
Tincturæ ferri chloridi, ℥v.
Liquoris acidi arsenosi, ℥jss.
Syrupi zingiberis, q. s. ad ℥iv. Misce.
Signa: One teaspoonful in water after each meal.

OBSTETRICS AND DISEASES OF CHILDREN.

1. Diseases in the mother liable to injure the fetus *in utero* are: Typhoid fever, typhus fever, scarlet fever, yellow fever, malaria, cholera, smallpox, measles, pneumonia, erysipelas, syphilis, chronic poisoning by lead, mercury, or phosphorus, albuminuria, cancer.

2. The structures composing the fully developed umbilical cord are: Two arteries, one vein, Wharton's gelatin, and a layer of epithelium.

3. The causes of labor at full term are not definitely known. Among the theories held, or factors supposed to be involved, are the following: (1) The gradual distention of the uterus at the end of pregnancy, after it has reached the physiological limit of its growth, while the contents still continue to grow. (2) The fetus becomes a "foreign body," and as such excites uterine contractions and is extruded. (3) Fatty degeneration of the placenta and of the decidua. (4) The circulation of toxic products in the placental blood acts upon a center in the medulla and so produces labor.

PHYSIOLOGY.

1. *Mucous membranes* consist of an epithelial surface containing glands, a basement membrane, supporting connective tissue, with blood and nerve supply. They are found lining passages by which the internal parts connect with the exterior of the body.

Serous membranes consist of a single layer of endothelial cells, with no glands, upon a connective tissue membrane, with blood-vessels, nerves, and lymphatics. They form closed sacs lining visceral cavities.

3. The normal pulmonary capacity in an adult is about 225 to 250 cubic inches. It is the sum of the Tidal air (about 30 cubic inches), the Complemental air (about 100 cubic inches), and the Reserve or Supplemental air (about 100 cubic inches).

PATHOLOGY.

1. In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may be* diminished.

2. The tissues surrounding an indolent ulcer are: Congested and edematous, with an overgrowth of connective tissue (the blood-vessels being compressed), the surrounding skin is apt to be pigmented, the papillæ are enlarged, and there is proliferation of the epithelial cells.

3. *Carcinoma* is apt to occur at a later age; is found in structures derived from the epiblast or hypoblast; possesses a fibrous stroma, in which are found both blood-vessels and lymphatics; metastasis is by the lymphatics.

Sarcoma is apt to occur earlier; is found in structures derived from the mesoblast; there is no stroma between the cells; the blood-vessels are in direct contact with the tumor cells; there are no lymphatics; metastasis is by the blood-vessels.

GYNECOLOGY.

1. Amenorrhea is the absence of menstruation.

It is *physiological*: Before puberty, during pregnancy and early lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes.

Treatment consists in: (1) Removing the cause, if possible; (2) general treatment by means of proper hygiene, rest, diet, bathing, attention to the bowels, exercise, etc.; (3) drugs reputed to be emmenagogues, such as iron, manganese, aloes, strychnine, apiol, oxalic acid, savine, rue, and tansy.

2. Alexander's operation is an extraperitoneal shortening of the round ligaments of the uterus.

Indications for Alexander's operation are: Retroflexion, retroversion, or prolapse of the uterus, when the appendages are healthy and the uterus is not bound down by adhesions.

3. *Prolapsus urethræ* is an eversion of the mucous membrane of the urethra through the meatus. It generally looks like a small tumor, which may become swollen, inflamed, and edematous; later on it gets excoriated. If the entire circumference of the urethra is involved, the tumor is dark and congested.

The condition may be mistaken for a caruncle or a polypus.

4. Acute Cystitis. *Symptoms*: Frequent urination, with tenesmus and a burning sensation in the urethra, later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

Treatment includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

PRACTICE.

2. The following table is taken from an elaborate one by Thayer:

TYPHOID FEVER.	MALARIAL (REMITTENT) FEVER.
Blood shows no leucocytes; eosinophiles diminished or absent; serum causes agglomeration of typhoid bacilli; malarial parasites and pigment absent.	Blood shows no leucocytosis; eosinophiles not notably diminished; serum does not cause agglomeration of typhoid bacilli; malarial parasites and pigmented leucocytes present.
Fever uninfluenced by quinine.	Fever disappears under quinine.
Usually epidemic; prevailing commonly in cities.	Is an endemic disease occurring particularly in rural districts; rarely epidemic.
Anemia absent, excepting in later stages.	Anemia more or less marked early in the course.
Characteristic roseola.	No characteristic exanthem; urticaria not uncommon.
Has a fairly characteristic course.	No distinct course.
Urine high-colored; bile absent; Ehrlich's diazo-reaction present during the height of the process.	Urine high-colored; may show a trace of bile; Ehrlich's diazo-reaction rarely present.
Onset gradual and progressive.	Onset generally intermittent.
The temperature does not reach 40° C. (104° F.) before the third or fourth day.	The temperature may arrive at 40° C. (104° F.) within twenty-four hours.
The apathetic expression of the face, the dryness of the tongue, and sordes upon the teeth are well marked and progressive.	These symptoms are not very marked.
Herpes rare.	Herpes common.

5.—

RHEUMATIC FEVER.	GONORRHEAL RHEUMATISM.
Generally attacks several joints and flits from one to another.	Generally monarticular (particularly favoring the knee).
Profuse acid sweats, fever, and rapidly developing anemia.	Symptoms are less severe.
	The disease occurs during or after a gonorrhea, and does not respond to antirheumatic treatment.

OBSTETRICS.

1. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death.

The line of *treatment* as laid down by Edgar is as follows: For *preventive treatment*: (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

3.—

Average capacity of child's stomach:	
At birth.	One and a quarter ounces.
Three months.	Four and a half ounces.
Six months.	Six ounces.
Twelve months.	Nine ounces.

5.

BRONCHO-PNEUMONIA.	LOBAR PNEUMONIA.
Generally secondary (to bronchitis or an infectious disease.)	Generally a primary disease.
Generally found in very young or very old.	Age has little influence.
Gradual onset.	Sudden onset.
Fever is not so high, and is irregular.	Fever is high and regular.
Ends by lysis, at no particular date.	Ends by crisis between sixth and tenth day.
Generally both lungs affected.	Generally only one lung affected.
Physical signs indistinct; and the evidences of consolidation are indefinite.	The physical signs are distinct; and there is a large area of consolidation.
Sputum is rather streaked with blood.	Sputum is rusty.

BULLETIN OF APPROACHING EXAMINATIONS.†

* No Reciprocity recognized by these States.
† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

South Dakota.—This State, after 1910, will require as a condition of admission to a medical college at least one year in a college of liberal arts, or its equivalent.

New York.—Among the new features in the law governing the practise of medicine in this State are the following: (1) The regents have power to revoke the license of a physician or annul his registration, or do both. (2) Physicians from other States may be excused examination if they have been in reputable practice for ten years and have "reached a position of conceded eminence and authority" in the profession. (3) There is no longer an examination on practice, therapeutics, and materia medica.

Therapeutic Hints.

Sweating Hands or Feet.—

℞ Pot. permangan.....gr. v.
Aquæ.....Oii.

or:

℞ Acid. tannici.....℥i.
Spt. vini. rect.....℥iii
Aquæ.....℥vi.

or:

℞ Quin. sulph.....℥i
Spt. vini. rect.....℥i.
Aquæ.....℥v.

The above to be used as lotions twice a day.

or:

℞ Bol. fulleri.....℥iii.
Bis. subnitrat.....℥i.
Acid. salicyl.....℥i.
Acid. tartar.....℥i.

M. Sig.: To be used as a powder.

THE OPPORTUNITIES OF A GREAT MEDICAL SOCIETY.*

BY THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

THE theme of my brief remarks this evening will be "The Opportunities of a Great Medical Society." This topic has been selected because an experience of four consecutive years, as your presiding officer, has forced on my notice some considerations bearing on the scope of our larger medical organizations, and this has seemed to me a proper time for expressing them.

But my remarks must be taken as suggestive merely, offering food for thought, if not for action.

There are, at present, four large medical bodies in this city: The New York Academy of Medicine, the County Societies of Manhattan and Kings; and this Association, which though not exceeding 650 in numbers, still is to be ranked, in point of size, with the other three. Each of these organizations assumes certain functions, duties and responsibilities, which are their distinguishing features.

But after all, I will venture to say, there are some general principles that should underlie all other considerations, governing the activities of each society, and I shall not claim credit for being the first to point them out. Along what lines, then, and in what manner is progress to be most profitably made?

Already in one section of this country there is a movement to have some sort of a post-graduate course for County Societies. Judging from a printed program, a County Society in Kentucky is to hold weekly meetings for this purpose, and on this one particular occasion the evening will be devoted to a symposium on such diseases as bone tuberculosis, bone syphilis, osteomalacia, and rickets. Presumably in each week of the months in which meetings are held, some subject of general interest to practitioners will be taken up and discussed in its several phases. This Kentucky Society is undertaking a *campaign of education*, and I take it, the plan may well serve as an example for other large societies, in which the general profession is interested. Of course, the precise method of carrying out such a plan will vary according to the special circumstances of each case.†

Supposing, however, that another course is pursued, and that a society undertakes, we will say, to "regulate the practice of medicine and surgery," holding out that among its prime objects are the prosecution of unlicensed or criminal practitioners, unregistered midwives, and medical impostors in general, it may always reasonably be objected that such a crusade, though laudable in theory and also in practice, if carried on with discretion and good faith, will still be open to the imputation that so-called *regulation* does not invariably regulate. Perhaps, too, some one may be bold enough to ask within what limits the society is proposing to exercise legal functions.

Law and medicine are two distinct fields. Certainly most members of these large societies, if the choice were offered them, would be apt to favor a preponderance of medicine rather than of law in their programs.

For we must first of all, in some way, keep abreast of the advances in the departments of medicine and surgery, if we are to practise with safety to our patients and satisfaction to ourselves. This is fundamental. No one of us has either the time or ability to cope successfully with even the principal problems that confront him. Even the specialist cannot do it in his own branch, while the difficulty of acquiring even a fair knowledge of new theories and practices is increasing day by day.

Such being the facts, and they cannot be refuted, it seems as if our larger medical bodies, representing as they do every phase of our art, may easily be the most important factors in disseminating this very important knowledge, and in the most palatable and digestible form.

Who that values his time does not prefer to spend a couple of hours in hearing some vexed question threshed out by experts, rather than to be forced to listen to a one-sided presentment of an unimportant topic, exploitation of immature ideas, or collections of ill-assorted facts.

Four years ago this Society, through its Council, undertook a campaign of education, and has kept it up year by year, only halting its scheme when the general public was looking for special information on such live questions as Pure Milk, Water Supplies, Disposal of Sewage, and the like; or the opportunity was particularly favorable for discussing more theoretical questions, such as Nutrition, Immunity, Pathogenic Protozoa, and so on, in which the profession at large is always profoundly interested.

More than this, who will not believe that opportune discussions on such public questions as Pure Milk, the Water Supply and Disposal of Sewage are not instrumental in shaping useful legislation, and that this Society did effective work thereby for the city, State and nation, perhaps.

Except for these occasional variations, however, the year has been divided in such a way that the entire fields of Medicine and Surgery have been systematically touched upon at their more important points: more time, of course, being given to general medicine and surgery, and less proportionately to the smaller specialties. For each session the best obtainable expert talent was secured, though in many instances we had to pass

*Retiring address by the president of the Medical Association of the Greater City of New York, February 17, 1908.

†Since the above was written a large number of county societies have taken up this idea.

beyond the limits of our membership. And yet every fellow qualified by experience to contribute was specially invited to do so; while the general discussion that followed was open to all.

As indicative of the efforts that have been made to secure the services of the best men, it may be said that more than fifty non-members have been invited in these four years to contribute to our programs, and they have represented a geographical area extending from Boston to Washington, and from Montreal to Savannah.

This statement also illustrates the fact, which is becoming constantly more evident, that many topics important for medical men to know can not be discussed advantageously without the help of laymen, of which the chemist, pharmacist, and civil engineer are good examples.

Fortunately the larger societies operating on this basis attract representative audiences, so that the lay specialist has an incentive to appear before them, particularly as reports of these meetings are published in our prominent medical journals and to some extent in the lay journals also.

Under these circumstances also, our larger societies should be more attractive than they are at present to the specialist, for they necessarily enlarge his field of view, which otherwise tends to become gradually smaller and smaller.

Most of us realize the close connection between general and special medicine, as well as between the theoretical and the practical. Examples are the relation between anatomy and surgery; between physiology, pathology, research work and clinical medicine. In fact, the more intimate these relations, the more favorably they react one on the other.

Medicine is both an art and a science. It has abandoned the realms of magic and mysticism, and is amenable to the same general laws that govern in the world of physics. It requires the same sort of apparatus, the same kind of reagents, and the same mental attitude and training that are essential for the physicist.

It follows naturally that a great society should be liberal. It has nothing to gain by putting up unreasonable bars. Singularly enough, we have never admitted women to membership, but on one occasion were glad enough to be instructed by a woman sent us officially as the Representative of the U. S. Government. And there are in this city to-day some women practitioners who are as well informed as any of us, in certain special lines.*

I will go a step further. But in so doing I am merely going to quote from my friend the President's address at the opening of the session of the one hundred and second meeting of the Medical Society of the State of New York, when, in speaking of our State organization, he stated that it "had one very definite purpose which made its first meeting a century ago significant—to associate all the reputable physicians of the commonwealth."

He adds: "I would bring every reputable practitioner in, simply drawing the line against those who for a very definite reason are unworthy, and so fulfill the purposes of the fathers."

Our State Society therefore fails of its original purpose so long as it undertakes to exclude any reputable licensed practitioners.

For more than twenty-five years some of us have taught homeopaths and eclectics in our post-graduate schools, have met them in consultation, and have ministered not infrequently to their physical ailments, and yet our societies have failed to accord them socially the position they legally enjoy. I would ask you to remember, however, that the bill requiring State examinations as a preliminary to practice in this State was passed *only* by the help of the homeopaths and eclectics. In the union of reputable licensed practitioners there is strength, rather than weakness. And I verily believe that if the representatives of our State and local societies had taken all of our licensed medical brethren into their confidence last year the Osteopath bill would never have been enacted in its present objectionable form. Past illiberality has excluded many of these men from our ranks; future liberality may bring them back.

There are now among us, unfortunately, in the public at large, some illogical, ignorant, or perverse persons who would like to set back the hands of the clock. They would, if they could, put an entire stop to animal experimentation; also to the use of the lower creation for medical purposes, though animals so employed have already been the means of saving thousands, perhaps hundreds of thousands, of human lives that would otherwise have been lost.

With a divided profession, the annual attempt to regulate vivisection by constantly increasing legislative restrictions is a perpetual menace to progressive medicine; with a united profession it might be a negligible quantity.

Another point that I will allude to briefly, is the great importance of the social element in a large society. Friendly greetings stand with some of us, for more than the scientific program. But whichever is placed first in any one's estimation, there is nothing but good to be had from a friendly word and a hearty grasp of the hand.

This social side of our meetings has been specially emphasized by our two extra Borough meetings this year, where the attendance was small enough to give each member the opportunity to meet and greet his fellows cordially, and yet large enough to encourage the speakers to put forth their best efforts.

I should be amiss if I failed to say that these large societies ought also to provide some practical protection for their members in the legitimate and proper discharge of their professional duties. In this connection I take pleasure in saying now that only once in the last four years has a fellow applied for legitimate relief. It was when his professional character had been unjustly assailed by the action of a city official. The matter was brought by the Council to the attention of the proper authority, and was promptly settled to the satisfaction of all concerned.

It must also be a matter of sincere gratification to us that during the same period not a single complaint was brought before the Council involving the character or conduct of any of the fellows. They seem to have been so impressed with the spirit of the golden rule that they needed no other.

I have a few words to say about the cost of membership. The founders of the Society wisely, I think, put the total annual charge for a member at the low price of $3.00, making the cost less than any other of the larger societies.

No practitioner can reasonably object to this low charge, and yet it helps to create a fund that is sufficient to provide us with at least twelve sessions in the year, publish our Transactions, defray all ordinary expenses, and leave a balance available for incidentals.

And now I will say, in drawing to a close, that

*Ten out of twenty-five of the reports published in a recent volume by the New York Department of Health (1905) were prepared by women practitioners in the employ of the department.

it has given me real pleasure as your President to meet and know so many, whose acquaintanceship and friendship I have learned to value.

Of course it goes without saying that the office has called for some expenditure of time and energy, and a trifle of substance, but the cordial support of my friends in the Council, on the Committees, and at our sessions, has much more than compensated for any personal outlay, while the growing interest in our doings, as shown by the gradually increasing attendance from year to year, has been a pleasant incentive for further effort.

But I want more especially at this time to thank the Council, one and all, for their uniform devotion to the interests of the Society, their regular attendance at its meetings, and their many useful and practical suggestions. The idea of holding four extra meetings annually in the Boroughs outside of Manhattan, inaugurated last month, originated with our esteemed and efficient Treasurer.

Our Corresponding Secretary has been diligent in season and out of season, ably filling the Presidential chair as occasion required.

Our Recording Secretary as Editor, has furnished us with the Annual Year Books, giving us well condensed and readable résumés of the association's work.

With these remarks I have relieved my mind of a weight that I now transfer to other and broader shoulders.

You will have a President who has all the qualifications necessary for maintaining a high standard of achievement; a membership that is representative of the best in the city; and lastly, a sufficient balance in the treasury.

Before closing I am going to venture the hope that the Campaign of Education that was inaugurated by this Society will continue to be a dominating feature; that its teachings will always be sound; its policies wisely aggressive.

One word more. There is an inevitable sadness on an occasion like this. Death has taken, in these few years, twenty-seven of our members from us. But they have "left on the shores of memory images and thoughts that shall not die."

Some names are entered on the rolls of fame. But the good deeds of none shall die forgotten

---

REPORT OF THREE YEARS' WORK AT THE SEA BREEZE HOSPITAL FOR THE TREATMENT OF SURGICAL TUBERCULOSIS IN CHILDREN.*

By LEONARD W. ELY, M.D., ATTENDING SURGEON,

AND

BRAINERD H. WHITBECK, M.D., ASSISTANT SURGEON

NEW YORK.

THREE and one-half years ago the New York Association for Improving the Condition of the Poor (the A. I. C. P.) began in this country the experiment of treating tuberculous diseases of bones, joints, and lymph nodes at the seaside, and opened its hospital on the beach at Coney Island. The widespread attention that this experiment has attracted, and the importance to the profession of an exact knowledge of the results attained have caused us to undertake the task of making a complete report of the work since its inception. Only those living in a great city like New York can realize the difficulty of tracing cases after they leave the hospital. The poorer classes seem to spend most of their time moving about; to trace them from place to place is an Herculean task. Had we been left to our own devices in this we should have failed miserably; but the A. I. C. P. has put its resources at our disposal, and its trained nurse, with admirable skill, has succeeded in locating most of the former inmates of the hospital and in persuading them to present themselves for examination.

When the hospital opened, on June 6, 1904, it consisted of ten tents with a capacity of fifty patients. In the fall, the patients were moved into the permanent buildings of the Society on the beach at Coney Island, and there they have since been quartered. From the start reliance has been placed upon two great therapeutic agents—fresh sea air and good food. How these are administered will be seen below. Everything else is subordinate to them. At first a physician resided at the hospital, but soon this plan was abandoned in favor of one providing for frequent visits by the attending physician and the attending surgeon. Only the smaller operations were undertaken at the hospital. For the more serious operations the children were transferred to the hospitals of Manhattan or of Brooklyn, and then were returned. This was made possible by the cordial cooperation of these hospitals and by the courtesy of their medical boards. A dentist has also regularly visited the hospital. In other words, the highest skill has always been at our disposal. To avoid mistakes in diagnosis most of the earlier cases were seen by at least one other surgeon besides the attending surgeon.

When the present attending staff took up the work, about a year ago, it threw out a number of cases, as will appear from the histories, that had been regarded as tuberculous. This had also been done by its predecessors. It has been our policy, when any case applies for admission, to try to demonstrate that it is not tuberculous before it is admitted. We have put the institution to a severe test, and have admitted severe, desperate, and even hopeless cases. Obviously, the results cannot be judged, therefore, on a percentage basis of cures. When we take in an emaciated child, riddled with discharging sinuses, and with amyloid viscera, we are simply adding another death to our list. It will be seen from our histories that we have often done this. One form of tuberculosis we bar—pulmonary.

It is not practicable to print our histories in full. They are much too voluminous. Each history of a case, as it appears here, is, in fact, an abstract; and in making these abstracts we have had two objects in view: (1) to give a general idea of the condition and course of a case, and (2) to give enough of the symptoms and physical signs to enable anyone who is able to judge of the correctness of the diagnosis. We do not ask anyone to accept our dictum as to diagnosis or final results. Possibly from the facts here set forth others will draw conclusions different from ours. We maintain the following:

(1) The seashore is the best place for treating children with tuberculous adenitis. The children make a better recovery here than elsewhere. Those with adenoids and enlarged tonsils should be submitted to an operation as a start of the cure. Sea air does not permit us to dispense with this.

(2) The seashore is probably the best place for children with tuberculous joints, provided they can have there the same skilled orthopedic care as elsewhere. Their disease runs a somewhat milder and

*Read at the meeting of the Orthopedic Section of the New York Academy of Medicine, January 17, 1908. The limitations of space have rendered necessary editorial condensation of the case reports in this article.

probably a shorter course, and the functional results are better than those obtained elsewhere.

(3) Our results have been largely due to the careful attention (including feeding and nursing) which has been given the children.

(4) Our results justify pushing the work.

(5) A hospital such as this does better work than a public hospital under control of the municipality.

(6) Many cases of so-called bone tuberculosis are in reality syphilis.

We do not know whether there is anything "specific" about the seashore, or whether children simply thrive better and so overcome more quickly their disease.

As to treatment other than diet and fresh air, little need be said. We use plaster when we can in preference to braces. In Pott's disease we use first the Bradford frame, then plaster jackets; in hip joints, the short Lorenz spica. In knee joint disease after the acute stages, we also use plaster-of-Paris. Patients with large cold abscesses are transferred to the Manhattan hospitals, where their abscesses are opened, wiped out, and sewn up again with proper aseptic precautions.

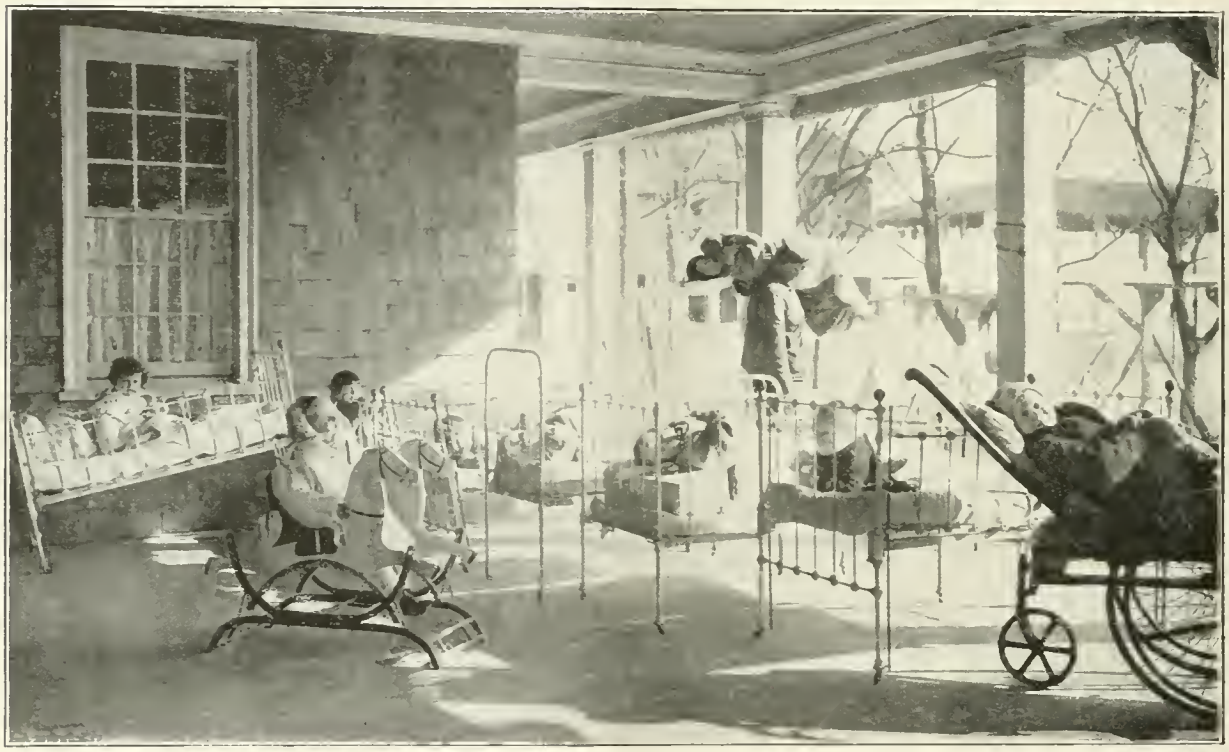

Fig. 1.—On the verandah in January.

The age limits are two to fourteen years. There are fifty beds. The medical staff has control of the admission and discharge of children. No patient is ever admitted without their consent.

Forty-two children are at present in the hospital. Eighty-two have been discharged. We possess histories of seventy-six of these.

Maggie B., 7 years. Admitted June 6, 1904. Discharged July 3, 1906. Cervical Pott's disease. Father probably died of tuberculosis. Patient has had measles, scarlet fever, and diphtheria. Two years ago her mother noticed that the child "rested her head between her shoulders." She took her to the Hospital for the Ruptured and Crippled, where a jacket and headspring were applied. These have since been worn. Child is poorly nourished and pale.

The course of the disease was uneventful. In the history we find notes of the straight back, restricted motion, etc. She wore her headspring for a year longer and was discharged cured, in good condition, and with very little deformity. Weight: on admission, 33 lbs. 9 oz.; on discharge, 42 lbs. 14 oz.

November 24, 1907. Child fairly well nourished, rather thin. She lives in most unsanitary quarters. She has a rather straight back, and the contour of her spine at the fifth cervical is broken. No other deformity is present, and function is perfect. This would appear to be a brilliant cure.

George G., 8 years. Admitted June 6, 1904. Discharged September 28, 1905. Diagnosis on admission, tuberculous adenitis; on discharge, syphilis.

George L., 2½ years. Admitted June 6, 1904. Discharged August 14, 1906. Tuberculous adenitis. Mother died of tuberculosis. Previous poor health. Had measles three or four months ago. After the measles a swelling was noticed on right side of neck. Child in fair condition, but anemic. Does not walk. In the right submaxillary region are several enlarged lymph nodes, and around them a puffy, soft swelling.

December 30. Both chains of postcervical glands much enlarged, also submaxillary glands on both sides. The boy improved in general health, but the lymph nodes remained about stationary until his adenoids were removed, May 20, 1906. Weight: on admission, 16 lbs. 11 oz.; on discharge, 26 lbs.

Wartburg Farm School, Mt. Vernon, November 14, 1907. Boy has been here for a year and has enjoyed health. He is now in good condition. One node the size of a bean on either side of neck just below angle of jaw. No other swollen nodes. No discharge from ear. Mouth breather. (Whitbeck.)

Bessie O'B., 13 years. Admitted June 6, 1904. Discharged June 5, 1905. Cervical adenitis; tertiary syphilis.

Petro A., 7 years. Admitted June 6, 1904. Discharged September 19, 1905. Tuberculous cervical adenitis. About ten months ago glands under right ear began to swell, and about five months later they broke down. A very complete operation was done at

St. Mary's Hospital four months ago, as appears from the history furnished by the hospital. Patient now has old open wound of operation posterior to lower third of right sternomastoid. Just behind the ear are three small discharging sinuses. One enlarged node in region of parotid, another under the chin. On the left side are two small nodules over mastoid, and a small scar over the parotid, still red.

September 19, 1905. Discharged cured. Weight: on admission, 40 lbs. 12 oz.; on discharge, 51 lbs. 8 oz.

Roosevelt Hospital, O. P. D., October 12, 1907. Glands under left angle of jaw slightly enlarged. Inguinal glands barely palpable; other glands not palpable. Old healed scar behind right angle of jaw and another over ramus. Spleen not palpable. Boy in fine condition.

Bennie M., 9 years. Admitted June 10, 1904. Discharged May 3, 1906. Tuberculosis of the left elbow joint. Family history of probable tuberculosis. The boy has had measles and pneumonia. The pneumonia was followed by an empyema which was drained. He has undergone four operations. About two years ago the left elbow became swollen and painful. It was operated upon in a hospital and has since been treated in a dispensary. Patient is poorly nourished. Left elbow is ankylosed. Small sinus is present, running down to the joint. Cicatrix of old operation wound in left axilla.

May 2, 1906. No pain nor evidence of active disease. About 10° of motion in the joint. Recommended for discharge—cured. Weight: on admission, 38 lbs. 8 oz.; on discharge, 45 lbs. 8 oz.

Roosevelt Hospital, O. P. D., October 8, 1907. Boy in fair condition. Fairly well nourished. Slight thickening about the left elbow, which is held in flexion. Old healed scar behind the internal condyle. No sign of active disease. No pain nor muscular spasm. Angle of greatest extension, 110°. Angle of greatest flexion, 75°. No rotation. Old scar of operation in left thorax.

Mariano A., 11 years. Admitted June 10, 1904. Discharged September 8, 1905. Tuberculosis of left ankle. About six years ago parents noticed that left ankle was inflamed. The disease grew worse and the ankle was operated upon four times in Italy and once at the Post-Graduate Hospital in this city. Afterward the patient was treated in a dispensary. Boy in poor condition; limps. Two deep wounds are present over internal and external malleoli of left ankle, from which an abundant foul discharge issues.

Discharged, September 8, 1905, cured. Weight: on admission, 64 lbs. 4 oz.; on discharge, 85 lbs. 2 oz.

October 6, 1907. Boy in fine condition; earns his living as coat-room boy; walks with barely perceptible limp. Foot is in slight calcaneo-valgus. Right calf measures 30 cm.; left calf, 23 cm. No motion in ankle joint. This is an excellent result.

Morris A., 5 years. Admitted June 14, 1904. Discharged June 30, 1907. Diagnosis on admission, Tuberculosis of lower end of left femur; on discharge, old osteomyelitis of left femur.

Fig. 2.—On the beach in winter.

Lucy E., 8 years. Admitted June 14, 1904. Discharged August 14, 1906. Tuberculosis of lower jaw. Duration of disease, one year. Child comes from St. Mary's Hospital, where she underwent two operations for her cervical lymph nodes and jaw. According to the history furnished us, carious bone and teeth were removed, and a mere shell of bone remained. Previous to this the patient had been operated upon four times at the New York Hospital. Child in good condition. Wound over left side of jaw discharging freely. Edema of right cheek. Wound under chin healed. Molars all gone on right side.

August 14, 1906. Discharged cured. Weight: on admission, 43 lbs. 12 oz.; on discharge, 62 lbs. 2 oz.

November, 1907. Child cannot be traced.

Joseph W., 5 years. Admitted June 14, 1904. Discharged December 13, 1905. Tuberculosis of inferior maxilla. Family history of probable tuberculosis. Duration of disease, seven months.

Patient has been treated at St. Mary's Hospital for two or three months, and has been operated upon there three times, as appears from the history furnished by them. Several pieces of necrotic bone were removed, and the right temporo-maxillary articulation was scraped. Boy is in bad condition; he can scarcely walk. Wounds under both sides of inferior maxilla are discharging pus.

The patient improved for a while; then his elbow and spine and finally his lungs became affected; and he went rapidly down hill and was removed on December 13, 1905, unimproved. He has since died.

David G., 10 years. Admitted June 16, 1904. Died, October 7, 1906. Left hip disease, etc. This was one of the desperate cases in which the effect of sea air was experimentally tried. He had had his disease for seven years, had been operated upon four times, and walked, on admission, with brace and crutches. His hip was suppurating extensively and had several sinuses. He was badly nourished and anemic. His liver was the seat of amyloid degeneration, and could be felt seven cm. below the free border of the ribs. His skin was yellow and pasty looking. His urine was loaded with albumin. The immediate cause of death was hypostatic pneumonia.

Florence V., 8 years. Admitted June 21, 1904. Discharged March 5, 1906. Diagnosis on admission, Tuberculous ulcers; on discharge, syphilis.

Kate B., 7 years. Admitted July 11, 1904. Discharged April 28, 1907. Tuberculosis of left knee.

Roosevelt Hospital, O. P. D., June 7, 1904. Family history and personal history negative. Scarlet fever one year ago. Four months ago, without known cause, the child began to limp and to complain of pain in left knee. The joint became swollen. She was treated at the Post-Graduate Hospital with a brace. Child in good condition; wears a brace which does not fit. Left knee swollen and flexed at 140°; its contour changed. Posterior subluxation. No motion in joint. Atrophy of thigh and calf.

July 11. Admitted to Sea Breeze. Child fairly well nourished.

January 10, 1907. Knee in slight flexion; slight thickening about joint. Patella slightly movable. Angle of greatest extension, 160°; of greatest flexion, 140°. To have passive motion.

April 28. Discharged, cured. Weight: on admission, 43 lbs. 4 oz.; on discharge, 58 lbs. 10 oz.

Roosevelt Hospital, O. P. D., October 11, 1907. Child in fine condition. Moderate limp. Left knee in slight flexion. Contour of joint slightly changed. Patella movable. Legs of equal length. Atrophy of thigh, 1¼ inches; of calf, ½ inch. Angle of greatest extension, 165°; of greatest flexion, 140°.

Here is a case that we can trace almost from the start. Doubtless it is to be regarded as an excellent result.

Margaret S., 5 years. Admitted July 15, 1904. Discharged December 21, 1905. Tuberculous peritonitis. Duration of disease, one year. Child is pale, emaciated, and weak, and walks badly. Abdomen is large, tense, resistant, and tender. The skin is brownish and dry. Enlarged lymph nodes in groin and in neck from the size of a pea to that of a hazel nut. Weight, 27¾ lbs. The patient had an almost constant diarrhea while in the hospital. Her lungs were found to be affected in December, and she was removed from the hospital. She died shortly afterward.

Fig 3.—A group of frame cases.

Florence, McG., about 2 years. Admitted July 20, 1904. Discharged December 2, 1906. Lumbothoracic Pott's disease. No previous history was furnished with this case except that disease had lasted for six months. On the history slip appears the fact that she has the "typical stoop," and that she is in poor condition and has a purulent otitis media. She was put on a modified Bradford frame and appears to have gone steadily downhill. Various abscesses developed, and on December 2, 1906, the child was removed from the hospital in very bad condition.

October 16, 1907. Child reported still alive, but very low. Sinuses still discharging.

Frank T., 3½ years. Admitted July 25, 1904. Spina ventosa or specific osteoperiosteitis.

September 4, 1905. Discharged, cured. Weight: on admission, 21 lbs. 11 oz.; on discharge, 31 lbs. 4 oz.

Charles O'C., 8 years. Admitted July 26, 1904. Discharged October 21, 1906. Right hip disease. Patient's father died of tuberculosis. Patient has been treated for past year at Polyclinic and Hospital for Ruptured and Crippled. About three months before admission here an abscess was opened in the thigh, and since then this has discharged through a sinus on the outer surface of thigh. General condition fair. Weight, 35 lbs. For a while after admission the child improved and gained in weight. Then the suppuration grew worse; amyloid degeneration of the viscera took place; and, on his removal from Sea Breeze, he was taken to Seton Hospital, where he died. This appears to be a case, not necessarily fatal on admission, which did not benefit from sea air.

Katie W., 6 years. Admitted July 29, 1904. Discharged April, 1907. Tuberculosis of left knee. Family history negative. Child had diphtheria last year. She has had measles. Last January child fell on iron grating, injuring her left knee. The injury was followed by some pain. Two weeks later the joint swelled and became tender. In February she applied at St. Mary's Hospital for treatment, and remained there eight weeks. Since then she has been at her home. Child in good condition; limps. No sign of abscess.

December 16, 1904. General condition good. Wearing Thomas brace with high shoe. R. A., 20; R. T., 13; R. K., 8⅝, 8½, 7¾; R. C., 8¼; L. A., 20¼; L. T., 12; L. K., 8, 8½, 7⅝; L. C., 6⅞; A. G. E., 180°; A. G. F., 135°. Brace removed. Plaster-of-Paris applied. The progress in this case was comparatively uneventful. The patient evidently improved steadily, as can be seen from the notes.

April, 1907. Discharged. Weight: on admission, 38 lbs.; on discharge, 48 lbs. 8 oz.

Roosevelt Hospital, O. P. D., October 9, 1907. Child in fine condition, goes to school, and walks and plays without limp. Knee in full extension. Slight thickening about the joint. Patella freely movable. Measurement show the affected leg one inch longer than the other; the left thigh one inch less in circumference than the right, and the left calf ½ inch less than the right. Full extension was possible, and flexion to an angle of 60°; *x*-ray negative. The beautiful result in this case might make one sceptical of the correctness of the original diagnosis; but the history, the lengthening of the affected limb, the atrophy, and the slight thickening cause us to concur.

Ellen F., 4 years. Admitted August 10, 1904. Discharged January 10, 1906. Tuberculous cervical adenitis. Mother died of tuberculosis. About one year ago some small, red areas were noticed in neck. They were not cared for and broke down. Child seems well nourished, but anemic. There are five areas of redness and induration in the cervical region in both sides, three of which are discharging. This child improved in her general condition, and on July 21, 1905, it appears that all her cervical nodes were healed. Shortly afterward one broke down and discharged for a couple of months.

Fig. 4.—A group with plaster jackets.

January 10, 1906. Discharged, cured. Weight: on admission, 27 lbs. 15 oz.; on discharge, 38 lbs. 8 oz.

Roosevelt Hospital, O. P. D., October 10, 1907. Child in fine condition; enjoys health; goes to school. Old healed scars in neck. A few small nodes palpable under left angle of jaw and a few in inguinal region.

Tom S., 5 years. Admitted August 20, 1904. Discharged December 31, 1904. Cervical adenitis. A brother of Florence S. Father died of tubercu-

losis in 1903. Six brothers and sisters dead of various diseases. Pneumonia at three years; measles; suffered from cough all last winter, and during this period mother noticed that child's neck was swollen.

Examination: Boy in good condition. Scattered along anterior margin of right sternomastoid muscle are small nodes the size of a pea or smaller. On the left side above the clavicle and anterior to sternomastoid muscle are nodes of various sizes. In the upper third of the muscle on this side is a diffuse soft swelling.

December 31, 1904. Discharged, cured. Weight: on admission, 44 lbs.; on discharge, 47 lbs. 8 oz.

Roosevelt Hospital, O. P. D., October 7, 1907. Inguinal, epitrochlear, and submental glands slightly enlarged and hard. Mouth breather, round shouldered. Old scar under the skin on the right side of neck. Examination shows the presence of adenoids. The boy also has frequent earache. Removal of adenoids advised.

Nathan N., 5 years. Admitted August 22, 1904. Discharged July 5, 1907. Left hip disease. Father has tuberculosis. Patient had pneumonia when two years of age. Two years ago patient began to complain of pain in left leg. This was followed by an abscess, which was opened at the Post-Graduate Hospital. Since then the boy has been treated at the dispensary of that hospital.

Examination: Child in poor condition. Operation wound still discharging on external surface of left hip.

December 30, 1904. General condition poor. Hip joint very sensitive. Profuse discharge from the two sinuses. The thigh is in flexion and marked adduction, and is one inch smaller in circumference than its fellow. Its range of motion is limited to 5°.

January 3, 1907. No sign of active disease. Marked thickening about the joint. The left lower extremity is an inch and three-quarters shorter than the right, and two and one-half inches smaller about the thigh. The angle of greatest extension is 180°; angle of greatest flexion, 160°.

July 5, 1907. Discharged, cured.

Roosevelt Hospital, O. P. D., October 7, 1907. Child in good condition. Small inguinal glands barely palpable on the right side. Marked limp. Left thigh in extension and slight adduction. The range of motion is increased to 90°. The left trochanter is one inch above Nélaton's line. Old scar five inches long over the external surface of the upper part of the thigh.

Freddie S., 3½ years. Admitted August 21, 1907. Discharged February 27, 1907. Left hip disease. Mother has pulmonary tuberculosis. Patient has previously been in good health. In the early part of January last he began to complain of pain in left leg, which rapidly grew worse; he screamed with pain when thigh was moved or touched. On January 9 he was taken to the Laura Franklin Hospital, and at that time had lost flesh and had a temperature of 104.5°, which later went to 105°. His urine showed a trace of sugar and of albumin. Blood count showed simple anemia. Spasm of muscles about hip. Late in January an abscess formed on right side of neck and burst. The temperature continued high until February and the child grew very thin. In March he began to improve. Now he is well nourished and has good color. He wears a brace but refuses to walk. The thigh is in abduction. Motion of it causes pain.

December 2. Thickening over trochanter. No sign of abscess. No atrophy of thigh. Angle of greatest extension, 175°; angle of greatest flexion, 90°.

January 10, 1907. Boy in excellent condition; walks without limp. Left thigh in indifferent attitude. Double knock-knee. No sign of disease in hip. Motion free in every direction. No thickening about joint. Left lower extremity is ¼ inch longer and left thigh ⅜ inch smaller in circumference than its fellow. "Child has probably never had hip disease" (Ely). The *x*-ray shows coxa valga and a darkening of the shadow of the neck on the plate.

February 27, 1907. Discharged, cured.

Roosevelt Hospital, O. P. D., October 1, 1907. Boy in fine condition. Examination gives practically same results as that of January 10. Absolutely no sign of disease. Spleen and lymph nodes normal; teeth good.

Here is a case with a fairly typical history of hip-joint disease. When we examined him carefully in January we scouted the correctness of the original diagnosis because there were absolutely no signs left of joint disease. But what else could it be? Certainly not a fracture of the neck, nor a strain, nor an acute epiphysitis, nor a gonorrheal joint. We are forced to the conclusion that it must be one of those rare cases of hip disease with complete recovery.

Willie H., 9 years. Admitted August 24, 1904. Discharged June 4, 1905. Tuberculosis of right shoulder joint. Family history negative. Two years ago without cause the boy began to complain of pain in his right arm. Eight months later swelling and redness appeared near the shoulder. One year ago he was operated upon, and three months ago the shoulder was operated upon again.

Examination: Boy in good condition. Apparent disease of the right shoulder joint. Limitation of motion. Sinus on the anterior surface of shoulder still discharging pus of foul odor. The rest of the operation wounds are healed.

June 4, 1905. Scars posterior and anterior to joints, about five inches long, healed. General condition excellent. No motion at the joint. One-quarter inch atrophy of arm. Discharged, cured. Weight: on admission, 57 lbs. 8 oz.; on discharge, 63 lbs. 2 oz.

Roosevelt Hospital, O. P. D., October 21, 1907. Boy in good condition; goes to school; enjoys health; no trouble with the shoulder. Marked shortening of the right humerus. Old scars in front and back of shoulder joint, one in axilla. The head of the bone is gone. Complete ankylosis. No sign of active disease. Left epitrochlear, left cervical, and inguinal glands on both sides palpable.

Margaret D., 3½ years. Admitted September 2, 1904. Discharged February 23, 1907. Tuberculosis of left ankle. Family history and personal history unascertainable. Child is well nourished; cannot walk. Five discharging sinuses about ankle.

The child was discharged, cured, on September 23, 1907, and was recommended to the Ruptured and Crippled Hospital for an operation to correct the valgus position of the foot. The shaft of the tibia was not thickened, nor did the *x*-ray show the thickening of an old osteomyelitis. The cartilaginous surfaces of the ankle were roughened.

This case shows well the value of conservative treatment in tuberculosis of the ankle. The patient had been operated upon several times at one of the large New York hospitals before entrance to Sea Breeze, and had finally been discharged because the parents would not consent to amputation!

Emil H., 13 years. Admitted January 17, 1905. Discharged December 21, 1905. Right hip disease; pulmonary tuberculosis; amyloid degeneration of the viscera. The patient has had hip disease for five years. General condition is poor. He is ema-

ciated, cachectic, and very anemic. Six sinuses are present in the region of the right hip. Spleen palpable 1½ inches below margin of ribs. Liver palpable 7 inches below ribs in midclavicular line. Surface of liver is smooth and the edges sharp.

The boy improved for a while. Then he began to go down hill very rapidly, and on December 21, 1905, he was discharged on account of pulmonary involvement.

The boy has since died.

James B., 9 years. Admitted January 30, 1905. Discharged November 3, 1906. Tuberculosis of right ankle. Boy comes from S. P. C. C. Previous history unascertainable. Duration of present disease, two months, with no history of injury. Wears Thomas brace; limps. Foot swollen and painful. In front of right internal malleolus is a discharging sinus. Motions limited in all directions in right ankle. One inch atrophy of calf. No glandular enlargement. Moderate anemia. Walking painful.

April 17, 1906. No pain; abscess healed. Functions of foot almost normal.

The patient continued to wear a brace or plaster until August, 1906. He was discharged "in perfect health" in November. Weight: on admission, 45 lbs. 11 oz.; on discharge, 58 lbs.

Roosevelt Hospital, O. P. D., November 16, 1907. Boy in good condition; goes to school. Small, unpigmented scar over internal malleolus of right leg. No sign of active disease. Motions free in all directions. Teeth good. Spleen normal.

Elsie K., 10 years. Admitted February 17, 1905. Discharged March 14, 1906. Left hip disease. On admission the condition of this patient was poor. There is no note in her history as to the length of time the disease had lasted, nor what had been its course. She had five sinuses which discharged freely. Her hip was in flexion and possessed only about 5° of motion. She ran a very severe course at the hospital and had much pain. On July 7 an abscess was opened in buttock, and ten ounces of pus was evacuated. The discharge from the sinuses gradually lessened, two of them healed, and the child's general condition slowly improved. She was removed from the hospital by her parents against advice. Improved.

Nathan S., 6 years. Admitted February 22, 1905. Discharged February, 1907. Tuberculosis of right ankle and of two fingers. Previous history unknown. Boy in poor condition; hops on left foot. Motion limited in right ankle. The astragalus is the seat of disease. One sinus behind interior malleolus.

The improvement in this case was steady and practically uneventful.

September 22, 1906, there appears this note: No sign of active disease. Leave off brace. Motion in ankle limited. Flat foot; build up shoe ¼ inch on inside.

December, 1907. Child cannot be found.

Max G., 5 years. Admitted February 22, 1905. Discharged September 1, 1906. Lumbothoracic Pott's disease. Patient's condition on entrance was very poor. He was emaciated, unable to walk, and weighed 26 lbs. 4 oz. His spine was extensively involved, and he had one discharging sinus in right thigh and a large abscess in left iliac region. A diarrhea was present with incontinence of urine and feces. His lungs were affected, either at the time of admission or soon after entering. At the time of the patient's discharge he was pronounced incurable, and the diagnosis then read: Tuberculosis of spine, of lungs, and possibly of intestines.

Died at Seton Hospital, July 9, 1907.

Minnie M., 10 years. Admitted March 5, 1905. Died August 20, 1906. Thoracic Pott's disease.

The general condition of the patient on admission was very poor. She was pale and anemic. Liver and spleen were enlarged and the sharp edge of the former could be felt at the level of the umbilicus. Lower extremities were edematous, and the lungs appear to have been affected slightly. One sinus was discharging in right gluteal fold. She weighed 19 pounds 4 ounces. Shortly before death an abscess ruptured into the rectum.

The cause of death appears in the history as Pott's disease, amyloid degeneration of liver, spleen, and kidneys, and hypostatic pneumonia.

John W., 8 years. Admitted April 8, 1905. Died July 19, 1905. Right hip disease, etc. Child emaciated and cachectic. Weight, 29 pounds 5 ounces. Sinuses discharging from right thigh; offensive odor. Heart rapid and regular. Lungs, puerile breathing. Liver and spleen enlarged. Hip very sensitive. Moribund, and admitted on urgent request of a member of the advisory committee.

The patient went downhill until death closed the scene.

Annie M., 6½ years. Admitted May 10, 1905. Discharged April 19, 1906. Right hip disease, amyloid degeneration, etc. Previous history unrecorded. On admission child was emaciated. Weight, 26 pounds 8 ounces. The hip was badly diseased and was discharging profusely from nine different sinuses. General glandular enlargement. Dilated, weak, rapid heart. Abdomen distended. Liver and spleen palpable.

The patient grew slowly but steadily worse. The amyloid degeneration became more marked, and on April 19, 1906, on account of pulmonary involvement, the child was removed to Seton Hospital and died there on September 29, 1906.

James B., 7 years. Admitted July 10, 1905. Died September 29, 1905. Left hip disease. Father and mother died of tuberculosis. Child is emaciated, weighs 31¼ pounds; does not walk. Hip very sensitive. Ulcer on right heel. Skin of back very tender. No motion in hip joint. Large, freely discharging abscess external to crest of left ileum. Swelling in left groin. Three sinuses leading down to abscess on inside of thigh.

Patient had foul discharge of blood and pus per rectum. He grew steadily worse. The cause of death on his history sheet reads: Hip disease. Complications, septicemia, amyloid degeneration of viscera. There was no autopsy.

Elmer C. Admitted July 16, 1905. Discharged November 4, 1905. Tuberculosis of left knee. Patient walked on crutches when he entered and was in fair condition. He had had his disease for 3½ years. Plaster-of-Paris was applied; but it appears from his history that he was cruel to animals and he was expelled from the hospital in disgrace.

Pasquale F., 3 years. Admitted August 8, 1905. Discharged September 25, 1906. Left hip disease. Duration of disease and course of treatment unknown.

Examination: Boy is in poor condition and unable to walk. His left hip is flexed at angle of 110° and possesses a range of motion of only about 5°. Joint is very sensitive. Three sinuses about the hip.

In the year that the patient was at the hospital he improved not at all. He has since died. The date of death is unknown.

Fred Q., 14 years. Admitted November 25, 1905. Discharged August 11, 1906. Tuberculosis of left knee. Tuberculous family history. Child has had

measles, scarlatina, diphtheria, and pertussis. Wears plaster-of-Paris on his left knee. No measurements or physical signs were taken.

August 3.—Atrophy of 2¼ inches in thigh and ¾ inch in calf. Knee in extension, 15° of motion. Slight swelling.

August 11.—Discharged, cured. Weight: On admission, 70 pounds 4 ounces; on discharge, 87 pounds 2 ounces.

December 1, 1907.—Boy in good condition; walks well, with no limp. Contour of left knee slightly changed. No fluid in joint; some creaking on motion. The knee is in full extension; flexion is slightly limited. Cervical and inguinal glands palpable. Teeth in good condition. Half an inch atrophy in thigh, and half an inch in calf. Angle of greatest extension 180°; angle of greatest flexion 75°.

Florence S., 8 years. Admitted November 26, 1905. Discharged January 28, 1906. Cervical adenitis. Father died of tuberculosis in 1903. Superficial glands, both submaxillary and both cervical chains, are palpable; also both inguinal.

January 28, 1906.—Discharged, much improved. Weight: On admission, 46 pounds 14 ounces; on discharge, 47 pounds 12 ounces.

Roosevelt Hospital, O. P. D., October 7, 1907.—Child in good condition. Mouth breather. Epitrochlear, submental, and inguinal glands slightly enlarged and hard. Examination reveals adenoids.

Willie S., 4 years. Admitted December 21, 1905. Discharged August 11, 1906. Cervical adenitis.

This patient had been treated for some time at the Woman's Infirmary. His general condition on entrance was poor. His cervical glands, anterior and posterior chains, were enlarged. Scar in front of lower attachment of sternomastoid with unhealed sinus in the middle of it. Both ears discharging freely; discharge has offensive odor. Scars: One on left buttock in gluteal fold, another external to this; one in right thigh just below great trochanter; one in right popliteal space; one over internal condyle. Teeth good. Tonsils hypertrophied.

August 3.—General condition excellent. Sinus healed. No evidence of abscess. Glands at angle of both inferior maxillaries palpable. Discharge recommended. Weight: On admission, 35 pounds 5 ounces; on discharge, 36 pounds 7 ounces.

Roosevelt Hospital, O. P. D., October, 1907.—Excellent condition. Slight general glandular enlargement—cervical, epitrochlear, inguinal. Scars all healed. Original diagnosis confirmed. Cured.

Grace M., 7 years. Admitted May 16, 1906. Discharged August 27, 1906. Cervical adenitis. Mother died of tuberculosis.

Duration of disease, one year. Various glands in neck and axilla enlarged. Excoriation around right ear. Opacity in left cornea. General condition fair.

Discharged improved.

November, 1907.—Child cannot be found.

Daniel R., 8¾ years. Admitted August 22, 1906. Discharged August 2, 1907. Congenital syphilis.

Joe R., about 7 years. Admitted August 22, 1906. Discharged August 2, 1907. Diagnosis: On admission, tuberculosis of the carpus; on discharge, syphilitic osteoperiosteitis.

John C., 9 years. Admitted January 2, 1906. Discharged April 4, 1906. Double hip disease; tuberculosis of right ankle; nephritis. Patient has been treated for past six years. General condition very poor. Weight 52 pounds 12 ounces. Inability to walk. Both hips in flexion, ankylosed. Many discharging sinuses from left hip. Tuberculous process in right tarsus and fibula excised, and foot in equinus. Urine loaded with albumin, 25 per cent. Prognosis: Surely fatal.

March 12, 1906.—Edema of both legs and feet. Removed from hospital.

Died at home about December, 1906.

Willie G., 9 years. Admitted March 6, 1906. Discharged June 1, 1906. Tuberculosis of right knee. General condition poor. The knee is ankylosed at angle of 175°, and in the neighborhood of the joint there are four discharging sinuses. Wears a Thomas knee brace. Atrophy of thigh, 2¼ inches; of calf, 1 inch.

May 30.—General condition much improved. Two of the sinuses are healed. Discharged at request of parents, to return to Ireland. Weight: On admission, 51 pounds 2 ounces; on discharge, 54 pounds 14 ounces.

November, 1907.—The boy cannot be traced.

Stanley H. Admitted March 30, 1907. Discharged May 29, 1907. Cervical adenitis. Of this patient we possess no reliable data as to the course of the disease. His cervical nodes were enlarged at his entrance, and he had two old healed scars.

Judith M., 3 years. Admitted June 23, 1906. Discharged September 26, 1906. Multiple sarcomata.

James McG., 11 years. Admitted July 27, 1907. Discharged September 27, 1907. Lumbar Pott's disease. Patient entered the hospital on crutches, pale and thin. A jacket was applied and the boy's condition improved markedly. He gained 6 pounds in two months, and then left on account of homesickness.

November 25, 1907.—A swelling which appeared several weeks ago in the boy's back, broke about one week ago, and is now discharging a thin serous fluid from an opening that looks like a pepper box.

Thirty patients were admitted in the early summer of 1904, and were discharged after a stay of two or three months. When the hospital moved into permanent quarters the number of patients was reduced from fifty to thirty, and was later increased again. We have been able to trace only eleven of these short-time cases. Two or three are manifest examples of incorrect diagnosis. Of the rest little is to be learned by a perusal of their histories. The time of their stay was too short to produce much effect. Most of them appear to have gained in weight while at the seashore, and the majority of the gland cases examined are now in good condition.

167 West Seventy-first Street.

SOME NEW FACTS REGARDING HEART DISEASE.

By SANITÄTSRAT DR. WACHENFELD,

BAD NAUHEIM, GERMANY.

Only a comparatively short time ago valvular lesions were considered the most important group of cardiac diseases. They were held responsible for a long train of various disturbances within the organism, and they were thought to be the cause of congestive conditions of the more important organs. The belief that the heart muscle was very infrequently the seat of disease was still prevalent in the seventies of the past century, but when, as a result of the severe epidemic of influenza in 1889 and the following years, many deaths occurred from cardiac asthenia, the profession came to the

conclusion that healthy heart muscle is at least equally, if not more important than accurately closing valves. The generally accepted views concerning the importance of valvular disease proper are very confusing. The reason for this may be found in the fact that we cannot readily abandon certain views too long held, many of the latter became dogma, and upon them theories have been built which could not easily be made to harmonize with certain undeniable facts. Work hypertrophy (increased work due to hypertrophy), and dilatation were the two dogmas which no one dared to assail nor question, and as long as we consider these relics seriously our search for more light will be of no avail.

Let us consider primarily what I shall term "work hypertrophy," or, as above said, increase, of the ability of hypertrophied muscle to perform more work. Granted that the cells of hypertrophic heart muscle are larger than the normal, no competent pathologist has ever to my knowledge claimed that this increased the strength or capacity for work, of the contractile element of such muscle. On the contrary, they are unanimous in the opinion that hypertrophied heart muscle tissue has pronounced degenerative tendencies. It is also certain that, as the muscle cells increase in size, intercellular connective tissue also increases considerably. This alone renders an hypertrophied muscle unable to perform even as much work as a normal one. Orth emphasizes in his work on pathological anatomy the inability of the hypertrophied heart walls to relax completely, and says that even the thin wall of the right heart shares this fate even when slightly hypertrophied. It is certain that a cardiac contraction depends upon the difference between the greatest relaxing and the greatest contracting ability of the muscle. The less complete the relaxation, the less powerful the contraction. In other words, a maximum degree of energy can be obtained only through a maximum relaxation and contraction. It is thus plain that an hypertrophied heart muscle cannot perform more work than a normal one; it can at its best only produce less. We may therefore safely claim that "work hypertrophy" does not exist. Many have heard this statement long ago, and I feel that I am not laying down anything new. Romberg says that he does not see why increased work demanded of the heart could result in hypertrophy of its muscle cells, and while he does not appear disposed entirely to deny the occurrence of work hypertrophy, he seems to doubt it very much. The work of Romberg and other noted authors plainly attests the difficulty with which we tear ourselves loose from old-established dogma. On one page one author claims that the occurrence of work hypertrophy is very doubtful and unlikely, and on the very next says that this condition assists at times in overcoming certain difficulties. Hypertrophy of the cardia should never be considered a source of increased power; we would surely not credit any other hypertrophied and consequently poorly nourished muscle with the ability to produce greater power. It cannot here be a question of hypertrophy, but one of profound disturbance of general metabolism with its accompanying congestion of cell material. This explains why cardiac enlargement is so rarely found alone, but almost invariably accompanied by more or less disease in other organs.

Not less than the dogma of work hypertrophy is the one of dilatation admirably suited to cloud our views regarding the true existing conditions. The blood circulates within a system of closed tubes and is therein kept circulating by the peristaltic action of the heart and arteries. We have at one end of this circulatory apparatus the capillaries, whose walls lack the necessary muscle to assist in propelling the blood; at the other end, to equalize this shortcoming, we have a strong muscularis, which has at one point developed into the still stronger heart. Their combined power supplies what the capillaries lack. The power evolved by the heart also propels the blood through the lesser or pulmonary circulation. The thin-walled veins must possess greater elasticity than the arteries; they must be able to accommodate, besides their blood contents, other substances which enter them through the capillaries from the cells of the various organs. Their walls must consequently be less tense and more extensile than those of the arteries, so that the entrance of these substances which come through the capillaries from the lymph channels may not meet with too much resistance when entering their lumen. It is very likely that the muscularis of the veins is so weakly developed on that account. Within the veins the blood column is propelled chiefly from valve to valve by cardiac contraction and peristalsis of the left side of the circulation, so the pressure under which the blood reaches the right auricle must necessarily be very low. It can, however, not be negative in the portion of the large veins proximate to the heart, as Jacobsohn has stated. The pressure cannot be negative in any portion of the circulatory apparatus. To provide such pressure it would be indispensable to have a vacuum at some point within the circulatory apparatus. It goes without saying that a vacuum within the circulatory system is not to be given even a thought. It is undoubtedly true that the blood, when it returns to the right auricle, does so under very low pressure; we may safely say under the remainder of the pressure which has propelled it through the heart, arteries, capillaries, and veins. Whatever the views on the subject are, it is accepted that the pressure within the great veins in their portion nearest to the heart is nominal. However we credit the blood which so enters the heart with the ability to distend it unduly and produce dilatation of its muscularis, in the same breath we admit, however, that this same muscle can drive into the aorta a column of blood under measurable and comparatively great pressure, without suffering any damage. How can these facts be made to harmonize? They cannot at all.

Let us now see how the heart could otherwise be distended and suffer dilatation. There is no other known force which could accomplish it. So we must deny that dilatation can ever occur. Extension of the limits of cardiac dullness which is often found on percussion is merely, when not due to hypertrophy, caused by a change in position of the organ. We often find post-mortem hearts, whose cavities seem enlarged, this is due to optical illusion; a cavity whose walls are collapsed seems smaller to us than one whose walls are gaping and permit a view of the interior. If the walls of heart cavities are more or less hypertrophied and for this reason incapable of complete collapse and coaptation, the cavity will appear large to the eye. Again, perfectly normal hearts may be of different dimensions. Both Hoffmann and Krause studied a long series of hearts normal in construction, to ascertain their dimensions, paying special attention to the cavities. They found that the capacity of one

normal heart was more than double that of another. Their researches proved that the capacity of the specimens examined varied between 160 and 360 c.c.

The weaker the heart, the more its musculature is diseased, the less the pressure under which the blood circulates. So we should not claim that a heart which has, even when pathological, the power, by contraction to raise a large column of blood into the aorta, to be so weak as to be dilated by the infinitesimal pressure of the return flow.

Our present views of the mechanism of valvular disease are defective in at least one cardinal point. When referring to this disease we lose sight of the fact that such a lesion never develops in an instant. We assume when speaking of aortic regurgation for example, that a certain quantity of blood flows back into the ventricle during diastole; further, that the ventricle is then unable to accommodate the inflow from the auricle, and that eventually congestion of the left auricle, and finally congestion in the pulmonary circulation ensue. It is unlikely that the blood will distribute itself in this manner in aortic regurgitation, so-called. It is possible that a few drops of blood regurgitate at the very beginning of the lesion, if the ventricular pressure will allow it, the pressure is undoubtedly higher at the climax of systole than is that within the first portion of the aorta. Now two conditions must be reckoned with:

1. The blood circulates in a constant stream through the closed system of tubes of the greater and lesser circulation. Every drop participates in this flow. Any quantity of blood which would by means of aortic peristalsis be forced back through the diseased aortic valve, would have to overcome the power of the circulating blood; this power is by the force of gravity exerted against quantities of blood ever so small. Through this, an at least appreciable portion of the power which might drive the blood backwards is balanced. This shows that blood cannot regurgitate through a damaged aortic valve in quantity sufficient to have any influence upon intraventricular pressure. During the next systole this small quantity of blood (if any returns at all) is forced again into the aorta, increased power of the systole not being at all required.

2. If really a small quantity of blood is held back as a result of aortic insufficiency, if it fails to travel with the wave which enters the aorta to carry the blood to the distant arteries, it is natural that so much less will appear at the left auricle when the cycle is completed. Should, however, through aggravation of the lesion an increasing amount of blood be kept back at the aortic valve and not reach in due time the distant arteries, a correspondingly still smaller amount would reappear at the left ventricle. This means that the circulation must slow itself, the contraction volume must become reduced. It is claimed that mitral insufficiency causes congestion of the pulmonary circulation. If we make this admission we must also admit that, if a severely damaged mitral valve allows 10 c.c. of blood to regurgitate into the left auricle, the influx from the pulmonary vein is hindered in proportion, that this produces pulmonary congestion, which in turn would cause a similar condition in the pulmonary artery. Accordingly the amount of blood in the pulmonary circulation would be increased 10 c.c., and the systemic diminished in proportion. During the next systole still more blood would be withdrawn from the systemic and transferred to the pulmonic circulation. In a few moments the volume of blood contained in the respective circulations would be altered very considerably if such could be the case. In reality the matter adjusts itself in a quite different manner. At the beginning, while the lesion develops it is possible that a small quantity of blood, a few drops perhaps, regurgitate into the auricle. The strength of ventricular contraction is thereby not influenced, because the residual blood in the left ventricle at the end of systole is neither increased nor diminished in volume, consequently only a few drops less enter the aorta. Subsequent ventricular contractions are merely a repetition of the previous ones, each time a proportionally smaller amount of blood reaches the left auricle after completion of the cardiac cycle, there just as in aortic insufficiency a diminution of the contraction volume develops, which leads to a satisfactory equalization of the conditions of fullness and pressure in the large and small circulatory systems. It is fortunate that the matter arranges itself in this simple manner. What would the ultimate results be if each systole would transfer from the greater to the lesser circulation a quantity of blood even so minute? That absolutely impossible conditions would result has not been overlooked. But instead of accepting the fact that in mitral regurgitation, through adaptation of the contraction volume to the condition, disturbances in the lesser circulation are compensated, the theory of "work hypertrophy" of the right ventricle was constructed. This condition was to occur just at the desired time and prevent the accumulation of blood in the small circulation. It is quite sure that in mitral insufficiency congestion of the lungs is observed; it is also true that this is accompanied by an hypertrophied condition of the right ventricle. These morbid conditions are not caused by the trouble at the valve, they are the consequence of abnormal metabolism induced by the slowing of the blood current in the lungs, or they are at the very least considerably influenced by this fact. *Ubi inflammatio ibi affluxus* was taught us while studying surgery; what are local inflammations other than locally disturbed metabolism? As in the case of the two above mentioned forms of valvular disease, all other forms, from the outset until accommodation of the circulation results, pursue the same course. This is also true of the stenoses. Neither dilatation nor work hypertrophy ever contributes towards accommodation; equalization of pressure is always due to a lessening of the volume of contraction.

As showing to what conclusions we may arrive if we try to explain the various phenomena of valvular disease upon the theories of work hypertrophy and dilatation, the following illustrations are of interest. A well known investigator, Rosenbach, ascertained that when the aortic valve of animals had been injured thus producing an acute insufficiency, the arterial system contained less blood, and the pulmonary circulation more than normally. He adopted the erroneous view that the explanation of this sudden and new blood distribution could also be applied in the case of disease of the human heart, in which the development of aortic insufficiency is always a slow and gradual process. He furthermore concluded that the ventricle, in order to overcome the disturbances caused on the one hand by underfilling of the arterial system and on the other by overfilling of the pulmonary circulation, must propel more blood than normally; also that here a simple dilatation would not suffice and that a special phenomenon occurs, which the author calls hyperdiastole. This is supposed to be an active dilatation, increasing the capacity of the

cavity, during which certain portions of the walls stretch a little more even than during passive dilatation. The ventricle is supposed to take then so to say a start in order to propel the blood with its usual energy. To accomplish this, work hypertrophy established itself, strange to say, at the desired moment in order to assist in the production of this very complicated biological phenomenon.

Another example of the errors to which belief in work hypertrophy and dilatation may lead, is shown in the statement that in mitral stenosis the left ventricle at times becomes smaller and atrophic in consequence of supposed continued underfilling. A long list of deductions, one more impossible than the other, most of them physical impossibilities, could be cited. They can be comprehended only when we regard dilatation and work hypertrophy as established facts. Added to this is the fact that the gradual development of valvular lesions has never been duly considered. Valvular lesions are always the result of infectious processes of the endocardium. If during the course of endocarditis excrescences form on a valve, or shrinkage occurs through formation of rear tissue causing a severe lesion, and if the contraction volume is so reduced in order to balance and distribute the circulating blood that proper oxidation is impossible, death must ensue. The various organs require for their life process a definite quantity of oxygen in a definite space of time. Now if the blood circulates very slowly, when the waves within the vessels are so short and shallow that too long a time elapses before the venous blood can exchange its carbon dioxide for oxygen, the various organs necessary to the life process cease to functionate. Valvular lesions which are not sufficiently severe to produce such a very material slowing of the circulation are never dangerous to life. They frequently produce no symptoms whatsoever. But if, upon a case of old cicatricial valvular disease, another disease supervenes, having also the tendency to slow the circulation, the degree of danger to life will naturally depend upon the combined severity of the old and new troubles and their ability to allow of proper oxidation of the body. It is consequently not correct to speak of "uncompensated" heart trouble. The supposed lack of compensation is nothing more than a second and independent disease supervening upon an old cardiac lesion. Both diseases act in a similar damaging manner upon the circulation. Accordingly the expression, "uncompensated valvular disease," has no *raison d'être*.

Regarding prognosis and therapy we should of course not expect that indurated valvular excrescenses can undergo any changes; perhaps recent vegetations are sometimes absorbed, although this is very doubtful. Diminution of a murmur does not prove a diminution of the lesion, and we must never judge from the murmur the extent of a valvular lesion. Our main endeavor should be to prevent the ever-present feature of valvular trouble, the diminution of proper oxidation of the body, from increasing through additional burdening of the circulatory system. As myocardial changes always accompany endocarditis, and the possibility exists that small latent foci may remain for years, we must primarily observe the action of the myocardium. These foci can be eradicated in only one manner (each case being separately considered), viz., by mild or strong stimulation of general metabolism by means of thermal baths, massage, and suitable diet. These are the only measures which assure any possible success. I do not care to be considered as if speaking *pro domo*, neither do I wish to deny or ignore that which for many years I have found beneficial, so I must say that owing to the many forms and grades of its natural thermal baths, Bad Nauheim is the best adapted for such a wide treatment of heart affections. I must however enter a protest against the belief prevalent in America, that the Schott method means Nauheim treatment. Schott takes the stand that hypertrophy of the heart is induced by means of gymnastics, and he hopes thereby to obtain more energy. I believe that I have shown that such a thing cannot exist nor take place.

It may be claimed that the general tone of a normal heart can be increased through a course of gymnastics, and that this would improve the strength of the contractile elements of that organ. This applies also to the body muscles and against it the following may be said. Every human being is endowed at birth with a maximum ability to develop his musculature. The muscles, including the heart, can develop only to the extreme limit of this ability. The condition necessary to a healthy maximum muscular development is normal metabolism, this simply means the conveyance of normal nutrient substances to the muscle cells, and normal removal of waste. This is important, as not a single cell in the entire body receives its nourishment other than through the lymph channels. The lymphatic clefts reach directly every cell of all the organs in the economy. The capillaries, however, reach only to the clefts. We must, for this reason, and for many others which do not come within the scope of this work, regard the lymphatics as the carriers of cell nourishment. The force which propels the lymph within the closed system of channels, is mainly derived from muscular energy. For these reasons active muscular work, or passive, massage, is necessary to healthy metabolism. Absorption of the nutrient moving material within the lymphatics can take place properly only when muscular relaxation and contraction normally alternate. Excessive muscular exertion causes congestion of lymph. I have in mind, in making this statement, the lymph stagnation often seen in the muscles of the legs after long marches, and the same condition in the arm after protracted fencing bouts. The heart performs always as much work as the nutrition of its cells will allow. Overstraining of the heart—and each muscular act intensifies and accelerates its work—must lead not only in the normal, but particularly in the diseased organ, to congestion of its lymph channels. We can, however, stimulate metabolism of the diseased heart if we increase to a maximum the period of rest between the contractions and retard its action. For these reasons digitalis, rest in bed, and thermal baths act invigoratingly upon the diseased heart, whereas it is always, and in any case, harmed or damaged by gymnastics.

Care of Defectives in Germany.—According to recent data there are now in Germany 116 cities with special schools for backward children. The total number of these schools is 203, and the number of pupils is 13,100. Berlin has 31 of these accessory schools.—*Science*.

Hospitals in Australia.—Here is a gem from the latest speech of a prominent member of the Parliament of New South Wales: "The present Ministry may blunder along for a few months, but while gazing at the stars they will stumble over the pebbles, and then the ambulance will take them to the hospital, where the grinning skulls of their predecessors are stored."—London *Chronicle*.

"THE FLOWERS THAT BLOOM IN THE SPRING"—WITH VARIATIONS AND DIGRESSIONS.*

By W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

Cynicism, scepticism, nihilism as to medicinal therpeutics have, probably, in certain quarters and at certain times, been manifest throughout the history of the healing art. Conspicuously exponential of such an attitude in the classic era stands the Bithynian Asclepiades. A sort of prototype of Paracelsus in his denunciation of the earlier masters, Hippocrates included, charlatan at least to the extent of exploiting the perennial maxim, *Mundus vult decipi*, his intimate association with such men as Cicero and Lucius Crassus indicates him to have been, nevertheless, possessed at once of ability and merit. He undoubtedly rendered good service to the noble but luxurious Romans comprising his *clientèle* with his measures of diet, exercise, baths, and frictions. Yet he was successful not because of his rejection of the Father of Medicine, but in spite of it; not on account of his neglect of drugs, but because the means he did employ were rational.

To Boerhaave, a veritable modern Galen, is attributed the statement that the utility of curative procedures begins and ends with "keeping the head cool, the feet warm, and the bowels open"—an utterance astonishingly cynical for the most renowned physician of the ages. But the world-famed Lyden master went farther than the limits of his dictum in his own practice; and he also overlooked the salient fact that throughout the century prior to his luminous career Jesuit's bark had been curing malarial diseases, and for two centuries mercury had been curing syphilis.

The nihilism directed toward medicinal therapeutics in our latter day is even more than ever before pronounced and general. So true is this that at the very outset a plea for the fuller recognition and more thorough investigation of plants as remedial agents is halted by scepticism's challenge, *cui boni?* Such a plea, to comprehend more especially our indigenous flora, the writer has contemplated. But, as he sets pen to paper, in the ears of his fancy rings the mockery of that snatch of comic opera so much in vogue a few years ago, "The flowers that bloom in the spring have nothing to do with the case"; or its more energetic paraphrase, "Bother the flowers that bloom in the spring!"

To dispose of this derisive and disparaging outcry, let us first of all cite some sources of the discredit attaching to vegetable remedies. One cause of such distrust is the uncertain quality of the plant itself, which in its commercial form may have lost in part or entirely its original medicinal virtue through improper collection or careless handling. Uniformity of action as concerns the crude product evidently depends upon where, when, and how it was procured, as well as upon the age of the specimen. It is well known as to plants employed medicinally that several of most common use are altogether more active in the recent state, and that nearly all of them deteriorate progressively with the lapse of time.

Again, reliability of effect is largely dependent upon the character of the standard preparation offered as representative of the powers of the plant. Very likely decided medicinal merit inherent in the crude drug is frequently lost in its pharmaceutic manipulation. Apropos of this probability, the writer would express his conviction that we have taken a backward step, have, indeed, virtually deprived ourselves of some valuable remedies, by our abandonment of the old-fashioned infusions and decoctions.

A source of neglect, perhaps, rather than of distrust, relative to vegetable materia medica is the wonderful expansion of synthetic chemistry. No thoughtful person would, of course, decry this marvelously fruitful movement. But, on the other hand, it should not become too exclusive. Nature will through all time retain her preeminence in the realm of chemical synthesis—the products of her laboratory will ever constitute the basis, indicate the law, and furnish the material for all human achievement in this limitless field of scientific endeavor.

Another cause of scepticism as to the medicinal value of plants is the apparent inertness of some to which positive remedial properties have been attributed. The factor of physiological activity is a strictly relative one, however. The question of dose is mainly involved. Every drug in an amount small enough will manifest no appreciable energy, and almost every drug in an amount large enough will show itself possessed of power to modify in some way our physical organism or its functions. But even when no immediate effect may be discernible from any practicable dose of a given drug, a very pronounced impression might be produced through its steady and prolonged administration. It would seem that involved in this principle is the possibility of large gains in the therapeutics of chronic disease, as will later be more fully set forth.

After all, disappointment as to the efficacy of drugs will be due not so much or not so frequently to their impotence as to our shortcomings of knowledge with reference to the indications for their employment. The warrant for the use of a medicine must rest in the conditions of the case in hand—as we understand the nature and features of disease more clearly and completely, the more unerringly we apply our remedies thereto. One would not be expected to display great accuracy of aim without a commanding view of the mark. So therapeutics must constantly follow in the wake of pathology. Disregard for this order of relationship would imply confusion of the logic of science with the caprice of hazard. In all reason, ignorance as to the cure of disease will maintain a fairly constant ratio of equality toward the ignorance existing relative to disease itself.

Medicine is but just accomplishing its transition from empiricism to science. Not only for forty years, but for forty centuries, had the angel of the healing art been wandering up and down the wilderness, a nomad of nomads, her home everywhere and nowhere, her sole habitation the enclosure of a tabernacle's unenduring and unstable curtains. Now she is conquering her promised land. Some time, perhaps ere long, nevermore to depart therefrom, she will enter her temple, the granite of whose walls will be knit into one with Zion's eternal rock. In any sphere of human activity whatsoever, a fundamental change of régime is signalized by a period of nihilism and chaos. Construction of the new presupposes destruction of the old. Russia in blood and ashes is the prophecy of a new-born Russia. In this philosophic conception we find an ultimate, a necessary cause of present-date nihilism in the province of medicinal therapeusis. Our new wine must be put in new bottles.

The central idea of the old system of medication

*Prepared for presentation to the Union County (Pa.) Medical Society at Lewisburg, Pa., October 24, 1907.

was *specificity*. The single aim was to establish that any given drug is useful in such and such diseases. The discovery of facts in this direction was purely accidental. The method of the late decades is to ascertain the physiological powers of drugs—to determine what they do when introduced into the system—to learn how they may be employed as instruments in the modification of bodily processes. Formerly medicines were mysterious, magic agents; now they are plain, simple tools. Of yore new seas of therapy were sailed at random and by chance; today they are navigated through means characterized by precision, accuracy, certainty.

Again restricting our view to the vegetable kingdom, which especially concerns us in this discussion, it may be remarked that in their way the superseded systems of medical botany were, despite glaring defects, quite comprehensive and complete. The early Hindoos and Egyptians were assiduous and proficient herbalists. Theophrastus, representing the Greek period; Dioscorides and the elder Pliny, representing the Roman period; Avicenna, representing the Arabian period, and the German group of the sixteenth century headed by Brunsfels, representing the modern period, worthily wrought in this field—are known and honored still. We owe much to these herculean pioneers. Stars of the first magnitude are they; and though old and distant, though dimmed and partially eclipsed, they send their rays across the ages even to us on time's outmost wave. But the light that leads us must come from newer, nearer suns.

Regarding medicines as the analogues of the craftsman's tools, some lacks and defects relative thereto may be noted. Classification has been studied and emphasized to the neglect of differentiation. Important, of course, is it to know the qualities of a drug which make it like certain other drugs; but just as valuable is it to know the properties which constitute a drug a thing by itself. So remedies should be investigated individually as well as generically. The carpenter not only has saws, he has different kinds of saws; he not only has chisels, he has various forms of chisels. A wider exploration of this department of materia medica would enhance greatly the precision of our therapeutics.

There are acute disease processes, and there are chronic disease processes. Likewise there are acute physiological effects of drugs, and there are, also, chronic physiological effects of drugs. Knowledge of the latter, of the chronic resultant of medicinal energy, is pronouncedly scanty. The reason is not far to seek—facts in this direction are hard to secure—the laboratory appliances and methods which yield such rapid and satisfactory returns in the field of the acute effects of drugs are but narrowly applicable here. Hence the propriety and urgency of gathering and preserving every shred of such data within possible reach. Laboratory mechanism and effort may, as we get farther on, be adjusted to meet more nearly the requirements of the case; but the problem will have to be largely worked out in actual medical practice. The game is well worth the candle, however. Any advances along the line indicated will compensate for all pains and endeavor expended in their accomplishment. The key to many a tightly locked *terra incognita* in the treatment of chronic disease may be the reward of patient, untiring delving in these mazy drifts.

In illustration of the points at issue in the foregoing discussion let us get back to "the flowers that bloom in the spring"—those of them indigenous to our own botanic section. The first to greet us is trailing arbutus—*Epigæa repens*—a close relative botanically as well as therapeutically of bearberry—*Arctostaphylos uva-ursi*. Like bearberry and buchu in its general diuretic action, what are yet its individual properties and its distinct indication as a medicine?

We next notice the yellow head of colt's-foot—*Tussilago farfara*. This plant has been used as a demulcent in coughs, and over long periods as an alterative in scrofulous conditions. It has been rather completely shelved by imputation of inertness. But, persistently administered, may it not in the long run modify vital processes as decidedly as the drugs more promptly energetic?

The pure white crown of bloodroot, *Sanguinaria canadensis*, catches our eye. Here is a plant of indubitable medicinal activity. It touches the borderland of the poisons; and what may kill a dog in the laboratory may cure a man in the sick-room. How general and superficial is our knowledge of the remedial properties of bloodroot!

The quaint, frail bloom of Dutchman's breeches, *Dicentra canadensis*, now is noticed. As Turkey or Squirrel Corn the tubers of this perennial have been employed as a tonic alterative. It is known that an alkaloidal active principle exists. A paragraph or two comprises the literature of the subject. When shall more be written thereupon?

The purple of crane's-bill attracts attention—*Geranium maculatum*—one of the astringent group. How does it differ in action from its fellows? and has it any virtue aside from that of tannic acid?

The showy gold of dandelion, *Taraxacum dens-leonis*, is seen everywhere. This was formerly in great repute as a diuretic, and as an hepatic corrective. It is much employed in Germany. Why should its prestige decline in this country, while it maintains its standing at the very Mecca of science?

In shady woodland nooks the deep, rich garnet of birthroot, *Trillium erectum*, drowsily nods. To the root astringent, tonic, expectorant, and alterative properties have been assigned. It is a popular parturient. The aborigines valued it highly. How many have heard of it?

Beneath its canopy of glossy green droops the waxen saucer of may-apple—*Podophyllum peltatum*—vegetable calomel it has been styled. Where do the respective spheres of it and its mineral analogue merge, and where do they separate?

On hillside and mountainside dogwood replaces the white of snow with the white of blossoms—*Cornus florida*, the neglected and almost forgotten ally of the cinchonas. May it not have been supplanted too completely? May there not be indications for its preferred use?

This list might be extended, but, as it is, it sufficiently serves our purpose of illustration. It will indicate, also, an immense field for research, a field rich in promise and accessible to all. In his retiring-president's address before the New York Academy of Medicine, Dr Charles L. Dana expresses the judgment that "to a very large extent clinical or descriptive medicine and gross pathology are a finished story." The statement strongly appeals to reason. But, howsoever that may be, certainly therapy is not a closed story. Here may a man toil and think a lifetime, sustained and encouraged in every perplexity by the consciousness that his labor will not be in vain. He who gives to a noble craft a new or an improved tool is a benefactor of his race.

Finally taking our leave from "the flowers that bloom in the spring," we insist that they *have* something to do with the case, and that neither retrospect nor prospect will warrant the sceptical interjection, "Bother the flowers that bloom in the spring!"

A PLEA FOR THE CORRECTION OF UTERINE DISPLACEMENTS.*

By FRANK H. HANCOCK, M.D.

NORFOLK, VA.

THE following paper is based upon a study of six hundred pelvic examinations made at the Outdoor department, St. Vincent's Hospital, Norfolk, Va. A number of these cases I have taken from reports of Dr. P. St. L. Moncure, of this city, to whose painstaking care in making up these records I am much indebted. In this number there are 213 displacements, 17 retroversions, 26 antedisplacements, and 15 descents. However, for purposes of critical analysis I have selected 532 cases, on account of the more definite history taken in connection with them and their more copious clinical notes. In these 532 cases, therefore, applying for the most part for the relief of pelvic pain, there were 147 cases of retroversions, 24 of antedisplacements, and 12 descents; 112 cases of endometritis, 43 of which were associated with perineal or cervical tears and relaxed vaginal outlet; 72 cases of pelvic cellulitis, pyosalpinx, ovarian cysts; 39 fibroids; 31 metrorrhagias, not associated with fibroids; 27 venereal diseases; 8 cases in which no trouble was found, or which may be said to have been neurasthenic; 7 cases; 8 cases in which no trouble was found, or There were 7 cases of cancer of cervix and body; 8 cystoceles, in one of which the uterus was prolapsed, and in another retrodisplaced; 6 cases of dysmenorrhea, not associated with the displacement; 1 rectocele, with the uterus in normal position. The rest of these were women at the climateric, with the usual nervous phenomena, hematomas, pregnancies, vaginitis, vulvitis, etc.

In view of the well-known etiological rôle that laceration of the perineum is supposed to play, it was a matter of profound interest to me to note that of the 147 retroversions only 40 were accompanied by discernible perineal or cervical tears; of the 12 descents only 5, and of the 24 antedisplacements but 6. In other words, of 183 displacements only 51 were associated with relaxed vaginal outlet, leaving 132 that were independent of perineal insufficiency. Of these 147 retroversions 57 women had borne no children, while of the 90 remaining cases only 50 showed a possible post-obstetric cause, and most of these were first-degree tears. Of these nulliparæ about 10 gave histories of previous pelvic inflammation or miscarriages, leaving 97, more than half, in which there was neither scar tissue, nor tear, nor tumor, nor any condition that could account for these displacements, except the inability of the uterine ligaments to support the uterus. For this reason any consideration of displacements that emphasizes perineal support of the uterus without giving due credit to the ligaments is a false doctrine. Nor am I trying to ascribe all virtue to the ligaments. In this series of 112 endometritis there were 43 perineal lacerations, some of them involving the levator fibers and adjacent fascia, and yet without hernia of pelvic contents in a single case. In one of these the rectovaginal septum was ruptured down to the anterior rectal walls, and deep enough to involve the attachments of the transversus perinei, and the deep perineal fascia, certainly deep enough to destroy the supporting functions of the pelvic floor, and yet after 12 years there was neither rectocele, cystocele, nor descent of the uterus.

It can hardly be said that these tears produced the endometritis, there being 69 cases of endometritis without perineal injury, and 40 nulliparous women, in practically every one of whom existed an endometritis. In these 600 cases, there were 8 cystoceles, with but one prolapse, and one retrodisplacement; and one rectocele, with uterus in normal position. I believe that in most cases the material effect, even of second-degree tears, is the appreciation upon the part of the patient that the orifice of the vagina is enlarged.

I do not believe that these tears should be let alone, but I am convinced, from what I have been taught, from what textbooks and medical journals have to say on the subject, that the symptoms directly produced have been greatly exaggerated. I have shown that in the majority of these 147 cases of retroversions there was no post-obstetric condition, even associated with them, that could account for the displacement, and even in those cases where the rent was sufficient to destroy totally the validity of the vaginal wall, as in the rectocele case, and the 6 cystoceles, the uterus was held by its ligaments in its proper position.

Acting upon the hypothesis of perineal support, many surgeons repair the perineum, leaving the uterus to take care of itself, believing they have removed the cause of the retroversion. When the pelvic fascia supporting the blood-vessels is torn, there may be some passive congestion of the perivaginal tissues, which may, in course of time, drag the uterus down, but that it does not usually do so is shown, I think, in these cases.

Dr. Charles R. Robbins, of Richmond, Va., in a recent address before the Academy of Medicine and Surgery of that city, observes that the sphincter ani muscles include the rectum in their sling-like support, as well as the vagina. I am not aware that that fact has ever been controverted. It was the knowledge, apparently, of the anatomists who named those muscles some generations ago.

It is a fact that most perineal lacerations are in the median line (Kelly and Noble and my own observation), and that the anterior fibers of the levator ani muscles, that hold the vaginal walls in apposition are more directly reached by lateral tears, tears that reach up into the vaginal sulci; but it is also a fact, as stated by Deaver ("Surgical Anatomy" and Gray's "Anatomy"), that the anterior fibers of the levator ani muscles are inserted into the central tendon of the perineum, though Mr. Robbins states that these fibers have little, if any, connection with the perineal body or the tissues interposed between the vagina and the rectum. I would be interested in knowing how he obtained that information.

If the anatomy of the female pelvis is as stated by Deaver and Gray, what else could happen when the perineal body is torn but that the muscular fibers connected with it should further pull it apart, acting in the direction of their bony attachments, giving the appearance of the relaxed vaginal outlet.

What are we to do with these displacements? Leave them, the uncomplicated ones? Many surgeons and gynecologists say so. Dr. Stuart McQuire advises noninterference where they are accidentally discovered and are not producing symptoms at the time, saying ignorance is bliss and wisdom would be folly. It is a sentimentally endowed organ, he says, and he would not direct attention to it—a policy of silence that was observed with the tuberculous, until later knowledge put a thermometer in the physician's hand and made him responsible for the failure or success of his case.

Dr. McQuire does not even advise bimanual replacement—as simple a procedure as that is—in these uncomplicated cases, but leaves the organ

* Read at the annual session of the Medical Society of Virginia, November 5 to 8, 1907.

prostrate in the pelvis. He operates when the persistent symptoms require treatment—that is, when congestion and hyperplasia have ensued, irritating the nerve filaments, pulling upon the ovaries, giving rise to lumbar and ovarian pain, leucorrhea, and an after-coming train of neuroses; and yet in the same paper in which he advises this course he complains, with remarkable inconsistency, as though some one were guilty of great dereliction, that "unfortunately most cases of posterior displacement are seen at a date when the primary cause has ceased to be active, and when pathological changes have become anatomical alterations, and a removal of the exciting factor then is insufficient to correct the trouble;" failing to observe that these simple cases he had dismissed with such complacency were the forerunners of the now anatomically altered ones. Dr. McQuire thus advises to leave these simple cases, and observes later that delayed treatment is responsible for organic changes in the retroverted uterus, which have now rendered that organ functionless. Alteration of structure precedes the production of symptoms, and thus anatomical correction is not always followed by physiological restoration.

Gwathmey of Norfolk, Bovée of Washington, Montgomery of Philadelphia, Morris of New York, and others teach the same doctrine. The cases that these gentlemen discover accidentally, which at the time manifest no symptoms, and which they pass by—do they know that these cases do not later fall into the hands of other gynecolygists when, "unfortunately, pathological changes have become anatomical alterations?" It is impossible to agree with these gentlemen, great as their authority may be.

How are so many cases without symptoms discovered? Healthy women do not present themselves for pelvic examinations without some discomfort in the pelvis. Practically every woman with retroversion, recorded in this series, had pelvic or lumbar pains, or both, and leucorrhea. And if there are no symptoms, the fact that drainage is interfered with, that the ovaries are lowered in the pelvis and pulled upon as the fundus of the uterus goes back to the sacral hollow, that sterility is associated with flexion, that flexion may be a factor in ectopic pregnancy and is a factor in general nervous disturbances, that the flexion may become such as to interfere with the circulation, giving rise to congestion and endometritis, that pregnancy may occur and trouble ensue—should not these considerations determine the value of early correction? Is a cystocele to be corrected to relieve residual urine, and a rectocele to facilitate the passage of feces, and is a uterocele to be left with its accumulation of mucus and cell débris?

Searching the upper abdomen to relieve the accidental conditions found there, these gentlemen are willing to leave the dangers of the pelvis which are perpetual, at least, if not pressing. Do reflex nervous disorders come only from the eyes? Are not the reflexes from a diseased pelvis analogous in giving rise to neuroses, and if so, might not relief occur from correction of the causative lesion?

Dr. Morris of New York, finding a retrodisplacement without complications, sends the patient to an eye specialist, and if refractive errors are found has them corrected and dismisses the patient. Conversely the eye specialist might refer his cases of strabismus and of iritis, with the same assurance of relief offered the displacement cases referred by Dr. Morris.

Why did not nature leave the uterus in the sacral hollow if it was advantageous to have it there, rather than, as at present, movable between the bladder and rectum? Of what use are the round ligaments and the uterosacrals, so amplified by Bovée? Is not the uterus less likely "to wedge its way through the vaginal canal," when it forms an angle with it, than when it is parallel with it? That uterine displacements are the cause of sterility is believed by our best obstetricians. Remembering the delicacy of the adjustment of the processes of reproduction, its failure often under conditions apparently normal, we should certainly do nothing to add to the complex processes already necessary to this end.

Statistics show that the fecundity of the American woman is below that of any other woman of the world, the average number of children being as low as 2.5 per marriage. Is not this a condition to be dealt with? Discounting the large number that insist upon defeating nature's great purpose, there are still a multitude seeking relief from sterility.

Flexions do not cause sterility by mechanical obstruction, as formerly supposed. Spermatozoa will pass any point that will permit the exit of menstrual blood, but the attending endometritis is a factor. Sims found fifty per cent. of his cases of sterility were associated with dysmenorrhea, or really endometritis.

In cases not due to infection endometritis results from interference with the circulation, with its attendant phenomena, proliferation of the glandular structures, and leucorrhea.

The epithelium that develops is of poor quality and embryonic in character, on account of venous congestion occurring in place of the arterial blood that supplies the normal endometrium, giving a shaggy, thickened, mushy surface, which the villi of the impregnated ovum cannot readily penetrate, as they must do if the ovum is firmly planted and properly nourished.

Again, the excessive secretion pouring from the utricular glands is apt to wash away the ovule, just as it often sweeps out of the uterus the spermatozoa ascending to the distal end of the tube.

Nature arranged that the spermatozoa should be deposited in the vaginal vault, and that the cervix should be immersed in this spermatic fluid, and any alteration of this arrangement is at least, as Bissell observes, "discouraging to fecundation" and should be corrected.

We should certainly not do less in the twentieth century for reproduction than was done by the Ancient Hebrews and the Homeric Greeks, as illustrated in their precepts. Remembering the happy reputation of Priam, with his many sons, we should seek to render less frequent the fruitless efforts of Phœnix in the same direction.

Abdominopelvic Orthopedics.—Honoré Soulié believes that relaxation of the abdominal walls and ptosis of the abdominal and pelvic organs should be treated surgically by whatever operative procedures are necessary to hold in position all the organs and close all the ruptures. We are all familiar with the picture of suffering that is presented by those women who suffer from this condition, producing a severe neurasthenia, with all its symptoms, mental and physical. The equilibrium of the abdominal organs is maintained by the folds of peritoneum which surround them and by the pressure of tension in the abdominal walls. The walls exercise an automassage which aids the function of the splanchnic organs. They improve the circulation in the pelvic and abdominal viscera, emptying the pelvic plexuses like an aspirating pump. These important functions are lost when the abdominal walls lose their elasticity. The effect on the general health results from the effect on the great sympathetic system and the arterial trunks of the abdomen. Visceral displacement ensues, with loss of function in the stomach and intestines, and pressure effects from the displaced organs. No form of treatment so far has given good results except the surgical.—*Archives Provinciales de Chirurgie.*

MEDICAL RECORD.

SWEATED INDUSTRIES AND THE HEALTH OF THE MASSES.

VERY low wages are productive of ill health and of physical degeneration amongst the workers themselves; that is to say, wages which are not sufficient to procure for the worker and those dependent upon him a proper amount of nourishing food and a fairly comfortable home. Sweated labor is, therefore, to a certain extent, a menace to the health of the entire community, for those who perform this description of labor, as a rule, work under unsanitary conditions and receive quite inadequate wages. Further, home work is the worst paid of the sweated industries, and is usually accomplished under circumstances which render it not only dangerous to the health of the workers themselves but a distinct source of danger to the public at large. Recently, attention has been acutely drawn to sweated labor in general, and to home work in particular in Europe and especially in Great Britain. The fact is recognized that living in crowded centres is playing the most prominent part in the physical deterioration that is taking place among civilized and industrial races, and is the chief cause of the great infantile mortality that prevails in cities. Extreme interest is consequently manifested in considering every possible cause which tends towards these ends, and in evolving measures to combat the evil. Sweated labor, and the class of work which is done at home are acknowledged to be factors in the problem, and the whole question is receiving earnest thought by medical men everywhere.

Perhaps, however, the matter is most urgent in Great Britain, at any rate, it is there that it has been chiefly discussed of late. During the past two years numerous exhibitions and meetings have been held dealing with sweatshop labor, and endeavoring to formulate a workable scheme, whereby the most obvious abuses of the system may be swept away or mitigated. In the *Lancet* of January 16, 1908, there appeared an article treating of women home-workers, written by a contributor who had just made a pilgrimage through those parts of London in which such workers most abound. The conditions discovered in these homes were unhealthy considered from any standpoint. In the first place, none of the women, with two exceptions, earned a living wage, the average being less than four cents per hour. Many had families to provide for, and the majority could only afford to hire one room. Some were compelled to work for fourteen hours a day, indeed to lead a life of almost ceaseless toil in order to support a bare existence. From the economical point of view a life of this nature cannot but be unhealthy. In addition to the fact that scarcely any of these female toilers earned enough to keep herself and her family properly nourished, the greater part of them were found to be living under decidedly unsanitary conditions. The rooms, or rather the room, in which the woman worker lived was invariably ill ventilated, dirty, and sometimes offensively foul. The conclusion reached by the writer in the *Lancet*, so far as the workers themselves and families were concerned, was that underpaid home work was injurious to the health of the workers and that it exerted a deleterious influence on the infant mortality rate.

How far home work amongst women is dangerous to the public health was another question considered and it was concluded that "under certain conditions infection may be spread by this means. Clothes handled, and left lying about in a small room in which measles, scarlet fever, or any other infectious disease was present might easily convey the disease to individuals outside." There would, thinks the writer, be little dissent from the view that home-work on clothes in some degree is a source of danger to the community. It may then be taken as proven that in Great Britain sweated labor and home-work amongst women are factors of some importance in the production of physical deterioration and in the causation of the high infantile mortality rate which is so constant a feature of life in manufacturing and overcrowded districts.

In this country conditions in this respect are, in general, somewhat better than those which exist in Europe. But in New York and Chicago there is a considerable amount of sweat-shop labor and home-work by women carried on in a manner calculated to injure the health of the workers and to be a source of danger to the entire community. In fact, although, perhaps, home-work among women in America is now a matter of little moment from a public health point of view, yet it is said that in some States women and young girls and even children are allowed to work under conditions which are likely to injure them physically and mentally. It would be no exaggeration to state that in every country of the world which is engaged in manufacturing there is room for great improvements in legislation dealing with factory and home work.

ARSENIC IN THE EARLY STAGES OF SYPHILIS.

EVER since mercury was first used in the treatment of syphilis various other drugs have at times been substituted for it. Thus in the sixteenth century guaiac was used, later sarsaparilla and sulphur cures came into vogue, and to-day the arsenical salt meta-arsenic-anilide, or atoxyl, is advocated by some. After the experiments at the Liverpool and the London Schools of Tropical Medicine had demonstrated the specific action of this drug on the trypanosome of sleeping sickness, and after it had been shown that an apparent relationship existed between the trypanosomes and the spirochete of

syphilis, it was quite natural that the same remedy should have been tried in syphilis.

In the *Wiener klinische Wochenschrift* of October 31, 1907, G. Nobl reports his results with the drug in forty-five patients, treatment having been begun in various stages of the disease. Recently infected patients with an initial lesion were treated by applying a wet dressing of a 20 per cent. solution to the eroded surface, as well as by injecting one-half a cubic centimeter into the lesion itself. The ulcer soon looked clean, but repeated examinations of surface scrapings, even after several weeks of wet dressings, showed many living spirochetes. The injection caused but slight local burning and edema which disappeared in a few days. Other patients in whom secondaries appeared in spite of the above treatment, and who then received three to five injections into the local lesion over a period of two weeks, showed no changes in the initial lesion except a little softening. When this softened lesion was excised smears still showed living spirochetes, and histologically it presented the same appearance as an untreated primary lesion. Still other patients received intramuscular injections, in addition to the local treatment, in order to ascertain whether these would prevent a generalization of the virus. In all of them secondaries appeared, though the patients received a total of one and a half to three grams of atoxyl, the eruption itself being no different from that in an untreated case. Twenty-eight patients who had received no previous treatment came to Nobl only after the appearance of secondaries consisting of erythematopapulous and papulopustulous eruptions, the patients having in addition either mucous patches in the mouth or perineal condylomata. They received two-tenths of a gram of a twenty per cent. solution until four or five grams had been given in all. After the treatment the secondary lesions still showed living spirochetes, and while some of the spots disappeared others showed only a central absorption while their marginal zones increased; in other words, there was no marked improvement. The buccal lesions were not benefited at all, in fact in some patients plaques on the palate appeared even during the treatment. In ten other patients in whom secondaries reappeared after mercury had caused their disappearance, the arsenical preparation was used, but had so little effect that mercury was again resorted to.

Nobl concludes that the drug has not the power to kill spirochetes, and since secondaries always appeared after local and general treatment, it is probable that it does not even inhibit the growth of the spirochetes or prevent generalization of the virus. When the latter had taken place secondaries did not disappear after the use of five grams, which is the average accepted maximum dose. In exceptional cases in which six to ten grams were given in all, the eruption disappeared but reappeared in two weeks. While Nobl had to stop the treatment in only one patient, on account of the appearance of a parenchymatous nephritis, other observers have reported albuminuria, gastroenteritis, chorioretinitis, and even amaurosis. Mercury, on the other hand, when administered soon after infection, usually prevents the appearance of secondaries or causes them to disappear when present. Furthermore the judicious use of mercury is rarely followed by any disagreeable symptoms, at any rate by no amaurosis. Uhlenhuth, Hoffmann, Roscher, Lassar, Lesser, and Metchnikoff have all reported good results from the use of atoxyl, but, as Nobl's report shows, unfavorable opinions as regards its curative effect in syphilis are not wanting. Until a wider experience shall have established the value of the arsenical preparation, if it ever does, we are not warranted in regarding it as a specific in syphilis or a substitute for mercury in the primary and secondary stages of the disease.

TREATMENT OF PARALYTIC TALIPES CALCANEUS.

Talipes calcaneus, though not one of the most frequent deformities caused by paralysis, is one of the most disabling. When the anterior group of muscles becomes paralyzed the foot dangles, and when the equinus finally becomes fixed the limb, though awkward, is still efficient. Not so when the calf muscles are paralyzed, as in talipes calcaneus, for then the propelling force is taken away and the patient walks heavily on the heel. The foot is useless except as a simple support. It is possible to prevent the development of paralytic talipes by supporting the foot in normal position, and even mild degrees of deformity may be successfully treated with braces. When, however, the characteristic deformity (cavus) with or without lateral displacement has set in, the brace must be strong enough to withstand the strain of locomotion, therefore so heavy as to be burdensome, and if lateral distortion is present satisfactory adjustment is difficult. Mechanical treatment thus becomes ineffective in a large proportion of cases and operative intervention becomes necessary. The objects of the latter are to restore symmetry and to increase the stability and resistance of the foot so that light apparatus may be effective in all cases and unnecessary in those of the most favorable type.

In the February number of *Annals of Surgery* R. Whitman describes his operation for this condition, having performed it with satisfactory results in over forty cases. The complete operation may be described as astragalectomy and backward displacement of the foot combined with arthrodesis, tendon transplantation, and tendon shortening. The author describes all its steps in detail as well as the other operations devised for this condition. Each of the other procedures has a certain merit in certain cases, particularly in those of mild type, in which the brace treatment is usually efficient; they are thus only an alternative for the latter mode of treatment. Whitman's operation, on the other hand, is efficient in the cases of advanced type in which the brace is inefficient. It is true that the removal of the astragalus shortens the limb, but it is essential to the restoration of symmetry and to the attainment of security. In comparison with these results the slight shortening, never more than one-half an inch, is of no importance.

Whitman's operation is unnecessary in those cases

in which the patient desires to do away with the brace, though the latter is efficient. Any of the other operative procedures may then be resorted to, as they are much simpler. When, however, the characteristic deformity incidental to functional use (cavus) is present, especially if there is also lateral displacement, the operation described by Whitman is certainly the most effective one. Hoffa employed it in the cases in which deformity and disability were most extreme and stated that his results were "ausgezeichnet."

The Fulguration Treatment of Cancer.

Although it is now some little time since de Keating Hart of Marseilles began to report the encouraging results he had obtained in cases of malignant growths by means of a form of electrical treatment to which he gave the name of fulguration, the accounts have been received with a certain amount of skepticism, which, as is usual, has been most pronounced among those whose experience in dealing with carcinoma is widest. The most important features of the procedure consist in the application to the diseased area of the extremely high tension sparks generated by the d'Arsonval or Tesla apparatus and emitted by a special form of electrode which is moved about over the surface involved at a distance of two to four centimeters, the patient being deeply anesthetized. After from five to forty minutes of this the diseased tissue is enucleated with the scalpel or is curetted away and the raw surface is subjected to a further period of fulguration in order to cause the death of any cancer cells that have escaped destruction the first time. The claims made in behalf of the method are being investigated by Professor Czerny in the Heidelberg Institute for Cancer Research, and in the *Münchener medizinische Wochenschrift*, February 11, 1908, he speaks of it as something deserving further study and trial. While de Keating Hart appears to be somewhat overenthusiastic in his views as to the indications for the treatment, Czerny states that there is no doubt that the sparks exert a selective destructive action on the carcinoma cells, at the same time stimulating the connective tissue to increased proliferation. Only superficial growths are suitable, but for these the fulguration may prove more satisfactory than the ordinary operations. In regard to the permanency of the apparent cures effected it is still too early to speak, as well as of the question of the treatment of deeper growths. In recurrences fulguration is of service in relieving the pain and the tendency to hemorrhage and suppuration, but whether it is curative is doubtful, while in advanced cases with much cachexia it may prove prejudicial through causing incomplete destruction of tumor cells followed by accelerated growth and an increase in the toxemia through the absorption of products from the disintegrated tissues. The technique of application also is not simple and requires many precautions with which only those accustomed to handling electric currents of high potential are familiar. The sanction of so high an authority as Professor Czerny will probably serve to stimulate interest in the procedure and enable the accumulation of sufficient data to establish its precise value and indications, though of course, years must elapse before it will be possible to arrive at a definite opinion in regard to the permanence of what apparent cures the fulguration treatment may effect.

The Treatment of Osteomalacia.

From this affection, rare in America but endemic in several European countries, some patients are known to recover spontaneously while others receive no benefit from any form of treatment. The treatment may be divided into surgical and medical, of which the latter should always be tried first in fresh cases, the former being reserved for the advanced cases and those treated medicinally without success. Among the drugs employed phosphorus is the favorite, but it requires a prolonged use during which patients may develop all kinds of deformity, and while the disease may be ultimately cured the deformity remains. Bossi introduced adrenalin with apparent success in several cases, and recently C. Merletti has reported the history of a florid case cured by this remedy (*Klinisch-therapeutische Wochenschrift*, October 21, 1907). He injected one c.c. of a 1 to 1,000 solution subcutaneously, once a day for twenty days, after which the patient was again able to walk. After an interval of ten days the patient was injected for another twenty days, when she was considered cured. Fehling thought that the disease was due to a disturbed function of the ovaries because it occurred at a period when they were especially active, and he therefore advised castration. This method of treatment gave good results in some cases reported by C. Everke in the August number of the *Monatsschrift für Geburtshilfe und Gynäkologie*. Out of forty-one cases, twenty were mild and are still under observation, being treated medicinally. Three others were cured by inducing abortion and in eighteen advanced cases castration was performed. Of the latter four women died a few days after operation, but the remaining fourteen were permanently cured, the oldest now having gone seventeen years without a recurrence. Soon after the operation the pains in the muscles and bones disappeared, and the bones becoming hard again. The patients who were unable to walk could soon get about again and attend to their work. A comparison of these experiences would seem to indicate a resort to adrenalin as a primary measure, although the cure is not always permanent, the disease sometimes recurring at a subsequent pregnancy. If this drug fails or if the diseases relapses, removal of the ovaries may then be performed.

Hospital Fare.

The question of hospital diet has been recently made the subject of considerable discussion, if it is allowable to speak of a discussion when the argument is all on one side, in *The Times* of this city. Several correspondents who have had the misfortune to pass longer or shorter periods as patients in the general wards or private rooms of hospitals have written in complaint of the fare that is provided in these institutions. The testimony has been all to the effect that the food is badly cooked and badly served. Hospital patients, as inmates of institutions in general, are proverbial "kickers," but there is reason to believe that in this instance there is some ground for their complaints. Incidental testimony on their side was afforded not long ago when an interne in one of the best appointed hospitals, smarting under the pangs of an unsatisfied palate, threw a pie out of the window at the head of the chef, who happened to be taking an airing in the yard, and bruised his scalp. The interne atoned for his reprehensible act by dressing the contusion of the chef and administering balm to his wounded

feelings, and so a scandal was hushed, but the protest against the poor table was eloquent. In the matter of general equipment our hospitals have nothing to fear in comparison with any in the world; the wards are light and airy, the beds are good, the operating rooms are perfect in their appointments, the instruments are of the best make, and the medicines conform in general to the standard of the Council on Pharmacy and Chemistry, although some which that infallible tribunal has condemned are in more or less extensive use, but the cooking is often very bad. In these days, when so much is being done in the way of nonmedical methods of therapy, there is no excuse for the neglect of dietetics. The matter is one that properly comes under the supervision of the medical staff and should not be left so wholly to the lay administration as it is.

"Dammed Circulation."

Not long ago Dr. A. R. Allen of Philadelphia, writing in the Medical Record on the proper term to express the therapeutic method known as Bier's hyperemia, proposed the adoption of the German name, *Stauungs-Hyperämie*. He examined all the English terms in use, such as passive congestion or hyperemia, stasis hyperemia, etc., and justly contended that none of them was suitable since none expressed the true condition. To this might be objected that neither does the German term express the true condition or any other condition to English ears, but an even more serious objection would be the difficulty of pronunciation; an English trained tongue would make a weird sound out of such a combination of letters—stawngs-hyperamy would be about the best the eye and tongue together could make of it, and the mental image it would call up would be about as clear as the average .r-ray picture. Dr. William Ewart, in *The Lancet* of February 22, suggests that we go back to the term "dammed circulation," proposed by Hugh Owen Thomas when advocating the method some thirty years ago. The term would doubtless be regarded as expressive by the patient undergoing treatment, and it would afford endless amusement to punsters in and out of the profession. But in spite of that it would be better than the German term; it means the same and the substitution of circulation for hyperemia is a distinct improvement. Obstructed or impeded circulation would convey the same meaning and this would be free from any possible objection that might be raised against Dr. Ewart's suggestion.

News of the Week.

Society for the Suppression of Unnecessary Noise.—This organization held its first annual meeting last week and has published its first annual report, in which Mrs. Isaac L. Rice, the president and founder of the society, describes the progress that has been made. One of the latest steps has been the organization, with the cooperation of the Board of Education, of a Children's Hospital Branch, whose members are pledged to make as little noise as possible in the neighborhood of hospitals. Mark Twain has accepted the presidency of this. The directorate of the society includes representatives from fifty-nine hospitals. In the one year of its existence the society has succeeded in getting a Federal law passed restricting signal whistling among the river shipping, in getting the Aldermen to pass an ordinance compelling teamsters to walk their horses in hospital streets, and in securing promises from the Board of Governors of the Automobile Club of America that they will endeavor to suppress all unnecessary automobile disturbances in the "quiet zone."

"Kommers" in Honor of Koch.—A very elaborate "Kommers" in honor of Robert Koch's return to Germany after his long sojourn in Africa studying sleeping sickness and rinderpest was held in Berlin on February 11. Among the very numerous guests were many of the most prominent scientists and functionaries of the Empire. The program included the presentation of a commemorative medal to Koch, as well as the singing of numerous serious and humorous songs relative to his achievements in the field of bacteriology and preventive medicine.

Crusade Against Cocaine.—The Illinois State Board of Pharmacy is waging war against the indiscriminate sale and use of this drug. Numerous inquiries have been received by the president of the board, Charles H. Avery, from wholesale and retail dealers, who have asked for an explanation of the provisions of the new cocaine law. Detectives are at work gathering evidence against dealers and agents who furnish the drugs to persons addicted to its use.

School Inspection.—The medical inspectors of schools in Chicago examined 7,166 children during the week ending February 15, and temporarily excluded 233 from attendance because they were a menace to the health and life of the other pupils. Twenty-five were excluded because of measles, ten for scarlet fever, twenty-six for chickenpox, seven for mumps, one for tuberculosis, and two each for diphtheria and whooping-cough.

Institution Treatment for Inebriates.—A bill prepared by Dr. DeLancey Carter of Brooklyn has been introduced into the Legislature of this State to establish an institution for inebriates with representative citizens as trustees. The bill provides for a systematic inspection of the prisons, jails, and penitentiaries, and the transferrence from these institutions to the inebriates' home of persons who are confined for habitual drunkenness. The institution will retain patients pursuant to the rules established by the State Board of Charities, receive patients, public and private, as the financial circumstances of each individual seems to warrant, and provide a systematic investigation of the large number of cases improperly diagnosed as alcoholic coma instead of concussion. The expenses of the institution will be provided for by a small percentage of the State excise collected in the city of New York.

Quintuplets.—From Steubenville, O., comes the report of the birth of quintuplets, whose aggregate weight was twenty-three pounds, while their mother is said to weigh only one hundred pounds. Three of the infants died within an hour, but the others are thought to have a chance of recovering. Two of the father's brothers have been the fathers of twins and two others the fathers of triplets. His first wife died, according to the newspaper account from which we quote, after having given birth to triplets.

Fire in New Haven Hospital.—On February 28 a fire causing damage estimated at $25,000 broke out in Grace Hospital of New Haven and made it necessary to remove the ninety patients in the building to places of refuge. As a result of exposure one patient has died and others are in danger. The students of the Yale Medical School, who were at recitation when the fire was reported, were dis-

missed in order to assist in the transportation and care of the patients. The fire started in the living rooms of the servants and the top floor of the building was destroyed.

The "Archives of Internal Medicine" is the name of a new journal published under the auspices of the American Medical Association. The journal will be issued monthly, under the editorial management of Drs. Joseph L. Miller of Chicago, Richard C. Cabot of Boston, George Dock of Ann Arbor, David L. Edsall of Philadelphia, Theodore C. Janeway of New York, and W. S. Thayer of Baltimore.

Concert Benefit for Augustana Hospital.—Recently the Swedish organizations of Chicago gave a concert benefit for this hospital, the proceeds of which amounted to nearly a thousand dollars.

Rat Catchers in San Francisco.—As a part of the vigorous prophylaxis against plague being carried on by the health authorities in San Francisco a corps of 200 inspectors and rat catchers has been organized, and a bounty is paid for the dead rodents.

Influenza in London.—The cable despatches state that London's grip epidemic shows no signs of diminishing, but is, if anything, increasing. Last week 126 deaths were reported in London as due to this cause, the record for the preceding weeks being 84, 34, and 32, respectively.

Yellow Fever in Cuba.—Yellow fever is said to be still present in Havana and elsewhere in Cuba. A private of the Fifteenth United States Cavalry died of the disease last week at Santa Clara.

Harvey Society Lecture.—The eighth lecture in the Harvey Society course will be delivered by Professor Ross G. Harrison of Yale University at the Academy of Medicine on Saturday evening, March 7, at 8:30 P.M. Subject: "Embryonic Transplantation and the Development of the Nervous System."

Carnegie's Gift to the Koch Institute.—Mr. Andrew Carnegie has announced his intention of giving the sum of $100,000 necessary to complete the amount of $250,000 required to endow the Koch Institute in Berlin for the study of tuberculosis.

Arrests for Failing to Wash Milk Cans.—The first arrests for violation of the new section of the Sanitary Code, which makes failure to wash milk cans a misdemeanor, were made on February 29, when East Side offenders were taken into custody and held in bail for trial. It is the intention of the Health Department to enforce this regulation strictly before the advent of the hot weather.

Ambulance Upset.—A Flower Hospital ambulance, which was conveying to the hospital an ironworker who had been injured on the Third avenue elevated structure at East Sixty-seventh street, was run into on Saturday by a Consolidated Gas Company wagon at the corner of Sixty-seventh street and Lexington avenue. The ambulance was overturned and the patient, who had a compound fracture of the leg, the surgeon and the driver were thrown into the street. The driver of the wagon was arrested.

Nassau Hospital in a Critical State.—In spite of the efforts that have lately been made to place this institution on a firm financial footing, there is still a possibility that it may be compelled to close, and a further appeal for contributions has been sent out.

Dr. Veranus A. Moore has been appointed director of the New York State Veterinary College, to succeed Dr. James Law, who retires in June. Dr. Law has been at the head of the veterinary college for the last forty years.

Banquet in Honor of Dr. Carmalt.—Dr. William H. Carmalt of New Haven was the guest of honor at a banquet held on March 5 in that city in commemoration of his long services as professor of surgery in the Yale Medical School, a position he relinquished last fall.

Diphtheria Death Under Christian Science Treatment.—A graduate from the Teacher's College of Columbia University who was engaged in settlement work on the East Side died of diphtheria last week. She was taken ill on February 8, and two days later her roommate sent for the patient's mother, who is a reader in the First Church of Christ in Philadelphia. For five days she treated her daughter according to the Christian Science methods, refusing to allow a physician to be called in, and then went back to Philadelphia, stating that the daughter was suffering from a mild attack of quinsy. As it was evident that the young woman's condition was serious, her roommate insisted on summoning a physician, who at once made a diagnosis of neglected diphtheria with severe renal involvement, and some days later the patient died.

Hillsborough County (N. H.) Medical Association.—This organization at its recent meeting held in Manchester elected the following officers: *President,* Dr. A. S. Wallace of Nashua; *Vice-President,* Dr. Eugene Wason of Milford; *Secretary-Treasurer,* Dr. E. Blaylock-Atherton of Nashua.

Death of von Esmarch.—The well-known German surgeon, Friedrich von Esmarch, for forty years professor of surgery in the University of Kiel, died in Berlin on February 23, at the age of eighty-five years. He had an unexampled experience as military surgeon, having served in many campaigns, and during the Franco-Prussian War was surgeon-general. His writings were largely devoted to surgical technique and war-time practice, and in 1873 at the Congress of the German Surgical Society he presented the elastic bandage for controlling hemorrhage to which his name is attached. In 1872 he married Henriette, Princess of Schleswig-Holstein. He leaves a son, Edwin von Esmarch, who since 1899 has been professor of hygiene in the University of Göttingen.

The Late Dr. Robert W. Taylor.—The following minute was adopted at the meeting of the New York Dermatological Society held on February 25: Dr. Taylor was one of the founders of the New York Dermatological Society, the oldest dermatological association in existence. Since its organization, in 1869, to the meeting held shortly before his death, and at which he was present, he has always been one of its most zealous members. An indefatigable student, an earnest and convincing teacher, and a brilliant and prolific writer, his death will not only be keenly felt by those who had the opportunity of working with him and profiting by the example of his energy and enthusiasm, but will be regarded as an irreparable loss to the medical profession. Among the eminent names which have been inscribed upon the muster roll of our society, Dr. Taylor's will ever rank high. No member has been more faithful in the discharge of his duties, and no one by his professional achievements has shed greater luster upon its membership. In our grief at the thought that he will meet with us no more we feel that we have lost not only a very distinguished colleague, but a most estimable friend. (Signed)

George Henry Fox, Hermann G. Klotz, Edward B. Bronson, Committee.

Obituary Notes.—Dr. Charles W. Sonnenschmidt of Washington, D. C., died on February 28, in his seventy-seventh year. He was a native of Germany, but came to New York when a youth. He was for many years on the staff of the Homœopathic Hospital.

Dr. Robert Luedeking of St. Louis died on February 29, at the age of fifty-five years. He was born in St. Louis and was the dean of the Medical Department of Washington University.

Dr. Charles F. Fitzgerald of this city died on February 27, at the age of thirty-five years. He was a graduate of Holy Cross College and received his medical degree from the College of Physicians and Surgeons in 1898. He was assistant surgeon to St. Vincent's Hospital.

Dr. John H. Coverly of Brooklyn died on February 25, at the age of sixty-five years. He was of Scotch birth, but had practised in Brooklyn for about twenty-five years.

Dr. Alfred T. Halsted of Newark died on February 24, at the age of forty-five years. He was graduated from the University of Vermont with the class of 1891.

Dr. John Prorasco died at Plainfield, N. J., on February 25, at the age of sixty-six years. He was graduated from the medical department of the University of Pennsylvania in the class of 1869. He entered the Bucknell University as a member of the class of 1864, and would have been graduated in that year, but the entire class enlisted in the Twenty-eighth Pennsylvania Cavalry at the outbreak of the Civil War.

Dr. Isaac R. Trimble of Baltimore died on February 24, at the age of forty-eight years. His death was due to an infection received while operating on February 10. He was born in Talbot County and was a graduate of Johns Hopkins University and the University of Maryland. He was a member of many professional and other organizations and was at one time dean of the Woman's Medical College and professor of anatomy and surgery in the University of Maryland. At the time of his death he held a similar post in the College of Physicians and Surgeons and was surgeon-in-chief of the Baltimore and Ohio Railroad Company and of the United Railways Company.

Dr. Vesta D. Miller of Needham, Mass., died on February 25 in Boston, at the age of sixty-four years. She was born in Ketchumville, N. Y., and was a graduate of the College of Physicians and Surgeons in Boston. For ten years she was professor of obstetrics and gynecology in that institution, and she was a member of many medical societies and other organizations.

Dr. Horace B. Wing of Los Angeles, Cal., died on February 13, at the age of fifty years. Dr. Wing was born in Collinsville, Ill., and received his medical degree from the Chicago Medical College in 1886. The following year he went to Los Angeles and had practised there ever since. For some years he had been professor of clinical medicine in the Medical School of the University of Southern California.

Dr. J. J. Crook of Leadville, Col., died in Glenwood Springs on February 15, at the age of eighty-one years. Dr. Crook was a native of Kentucky and had served as surgeon during the Civil War. He then removed to Leavenworth, Kan., and was twice elected to the Legislature. In 1875 he went to Colorado, going first to Denver and four years later to Leadville.

Dr. George E. Ehinger of Keokuk, Iowa, died in West Chester, Pa., on February 14, at the age of eighty years. He was born in Germany, but came to this country in 1833 and was graduated from Western Reserve University in 1853. After practising for a time in Lee County he removed to Keokuk in 1864, and had continued in active practice until about four years ago, when he retired and removed to West Chester. He was an ardent botanist and some years ago presented his collections to the Keokuk High School.

Dr. William H. Semple died at Philadelphia on February 27, at the age of forty-three years. He was graduated from the Medico-Chirurgical College in the class of 1898.

Dr. Daniel S. Greenwald died at Philadelphia on February 20, at the age of fifty-five years. He was graduated from Jefferson Medical College in the class of 1885.

Dr. Alexander S. McClean of Springfield, Mass., the father of Dr. George C. McClean of the same city, died on February 22 of heart disease, at the age of eighty-seven years. He was a graduate of the Medical School of the University of Pennsylvania and had practised in Springfield for many years.

Dr. John C. Johnston of Butte, Mont., died on January 28 of diabetes at the age of fifty-eight years. He was born in Connellsville, Pa., and was graduated from Jefferson Medical College in 1874. He came to Montana in 1878 and, after practising for a year in Phillipsburg, removed to Butte.

Dr. S. F. Wentworth of Minneapolis, Minn., died on January 31 at the age of seventy-two years. He had practised in Minneapolis for twenty-six years, coming there from Malone, N. Y.

Dr. Cyrus T. Kimmel of Kansas City, Mo., died on February 1 at the age of seventy-five years. He had been a resident of Kansas City for over twenty-five years, having formerly been in practice in Brunswick, Mo. For the past year he had been an invalid.

Dr. Frank P. Leckner of Detroit, after a long illness, died on January 28 at the age of forty-two years. Dr. Leckner was graduated from the Michigan College of Medicine in 1893 and had practised in Detroit for fourteen years.

Dr. Douglas S. Flewelling of Somerville, Mass., died on January 31 at the age of forty-seven years. He was born in Clifton, Md., and was graduated from the New York University Medical School in 1892, shortly after which he began practice in Somerville.

THE SEVENTH HARVEY SOCIETY LECTURE.

The seventh lecture of the present series given under the auspices of the Harvey Society was delivered at the Academy of Medicine on Saturday, February 22, in the presence of a large audience. The speaker, Professor Otto Folin, of Harvard University, took as his subject "Problems of Chemistry in Hospital Practice," and began by discussing the organization of the biological laboratory and its relation to the hospital.

Very few of the hospitals in this country were properly organized in respect to their biochemical laboratory. Perhaps this was due to the fact that so few men were really fitted for the positions he had in mind. The biochemical laboratory and the hospital should work hand in hand. There should be a trained biological chemist at the head of the

laboratory, and he should have entire charge of the work in the laboratory. A number of wards should be set apart for his special investigations, and he should be given every facility for working out his problems, independently of any other medical officer of the hospital. It was important to realize that research work of the highest kind could not be done under direction of any one save the person working out the problem. Studies of this sort could not be planned out beforehand, but must be left to develop themselves. While the biochemist would, therefore, cooperate with the attending physicians and surgeons, he should be left with the entire direction of the researches.

At the present time, according to the speaker, there was but one large American university which devoted itself to turning out men fitted to lead work of this kind. The ordinary chemist could not take up these problems because he knew almost nothing about physiology, and similarly the physiologist would not fill the requirements because he did not know how to work practically with his most important tools. What was needed was a man trained thoroughly in both branches. The demand for such men far exceeded the supply. The speaker said that any one of the biological chemists now engaged in this work could have changed his position twice or three times in the past year, so great was the demand.

Professor Folin then discussed metabolism studies. Until recently such studies were generally based on observations on the nitrogen equilibrium. This, he had repeatedly pointed out, was not a sound basis. There were many other factors which should be considered. He believed that the near future would show that much of the work on this subject which had been done in the past twenty years was worthless. It would also be shown, the speaker believed, that a study of the neutral sulphur, of creatin, creatinin, and of the undetermined nitrogen would yield a great deal of valuable information. In making analyses of the urine, too much stress should not be laid upon the necessity for working with the mixed urine passed during the entire twenty-four hours. The ordinary method of urine examination was worse than useless, for it often led to fallacious conclusions. The speaker illustrated this with a number of examples.

The analysis of the urine in diabetes was discussed, and especially the presence of acetone, about which so much had been written. In the speaker's experience he had never found acetone in the urine of a diabetic subject provided the examination was made on the freshly voided specimen. The peculiar sweet odor of the breath of diabetics had also been referred by many to the presence of acetone. Professor Folin did not believe that the odor came from the breath, but came from the stomach, and it was not due to acetone.

Among the interesting problems which the biological chemists were now studying was the question of the metabolism in typhoid fever, and the best diet for those suffering from this disease. To the speaker's knowledge, three different laboratories had recently investigated this problem and would soon be ready to publish their results.

In closing the lecture the speaker expressed his belief that the most promising field of medical research at the present time was that now presented to the biological chemist.

The thanks of the members of the Harvey Society was moved by Dr. P. A. Levene, who spoke of the revolution which Professor Folin had made in the analysis of urine, and of the stimulating influence which that investigator had exerted on biological chemistry applied to medicine. The chairman, Professor Graham Lusk, spoke in a similar vein, and referred to the work now being done in the metabolism of typhoid fever. He had himself tried to investigate this subject some years ago, but the number of difficulties presented by the present organization of hospitals made the work practically impossible to carry out. Thus it was almost impossible to obtain regularly twenty-four-hour specimens of urine from the patients. Some orderly or other was always forgetting or throwing the specimens out. Professor Lusk also gave a humorous description of the difficulties which had attended some studies on the metabolism in dogs, in which it had also been hard to obtain full twenty-four-hour specimens.

The next lecture of the series will be held on Saturday, March 7. The speaker will be Professor Ross G. Harrison of Yale University, and the subject, "Embryonic Transplantation and the Development of the Nervous System."

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent)

ROYAL COLLEGE OF SURGEONS, CURATORSHIP, APPOINTMENTS FOR MEMBERS, ETC.—CONGENITAL STENOSIS OF PYLORUS.—NUTMEG POISONING, CHEMISTRY OF THE OIL.—ARTERIOSCLEROSIS.—OBITUARY.

London, February 14, 1908.

At yesterday's meeting of the Council of the Royal College of Surgeons there was an unusually full program.

The council appointed Arthur Keith conservator of the museum in succession to the late Prof. Chas. Stewart. Mr. Keith graduated at Aberdeen in 1888 and after some years work abroad engaged in research work in the college and other London institutions, taking the F.R.C.S.. In 1895-6 he became demonstrator of anatomy and curator of the museum at the London Hospital Medical College and lecturer on anatomy in 1899. He is an active member of the Anatomical, Zoological, Anthropological, and other societies, and the author of numerous papers relating to anatomy, human and comparative.

A form of circular was agreed to and ordered to be sent to Fellows and members asking their opinion as to whether or not women should be admitted to examinations for the college diplomas. It was decided to inform the College of Physicians that further steps in the matter would not be taken pending the result of this inquiry.

A memorandum was also adopted to be sent to hospital authorities on the question of the rights of members to be candidates to appointments equally with university graduates.

Mr. Watson Cheyne, C.B., F.R.S., was appointed Bradshaw Lecturer and Dr. Ward Cousins representative on the Midwives' Board.

A small committee was appointed to keep the council informed as to what is being done from time to time regarding the medical inspection of school children and the arrangements for teaching elementary hygiene in training colleges and schools.

The Society for the Study of Disease in Children has had a very interesting discussion on congenital stenosis of the pylorus. Dr. Geo. Carpenter related in full detail a case in an infant of two months, breast-fed for a week, but then the bottle being substituted, it was sick after every kind of food, wasted and weak from starvation to such a degree that it looked as if it could not survive another night. The typical pyloric tumor was found, as large as an almond, hard as gristle, and there was gastric peristalsis in its direction. May 22 to June 6 gastric lavage and two-ounce feeds of whey were tried without benefit. Next humanized milk was given for a week. Then milk diluted with double the quantity of water was tried in two-ounce to three-ounce feeds. After a week of this the infant "began

to forge ahead" and is now well. Dr. Carpenter insisted on the importance of detecting the pyloric tumor. Otherwise one could not be sure that a case was hypertrophic. Spasm produced similar symptoms—vomiting of accumulated feeds, gastric peristalsis, etc. But he held the hypertrophic form was an abnormality of development and not a result of spasm, as some have supposed. Microscopically he had seen the pylorus muscle and more or less of the stomach muscle near it hypertrophied. Yet he thought dyspepsia was at the root of the evil, and if that were cured the tumor could be let alone. The most hopeless looking cases should not be abandoned by the physician. If the surgeon were called in, better late than early. It was possible cases cured by the physician might recur later, as Seefisch had reported three such cases operated on before the twelfth year. Even so the mortality would be less at that age, so that it was better for the infant to postpone the operation.

Dr. Edmund Cantley read a paper on the pathology of the disease. He did not believe spasm gave rise to hypertrophy. Recovery from spasmodic cases, mistaken for hypertrophy, led to an unduly favorable estimate of medicinal treatment. True hypertrophy is peculiar to the first few months of life and it varies from a degree of hyperplasia, which is fatal unless surgically treated down to a slight degree compatible with life if no secondary effects occur, *e.g.*, dilatation of stomach, gastric catarrh, and sometimes acute edema of the pyloric mucosa from muscular contraction. This contraction might be so slight as only to prevent sufficient food passing, yet the cases died from marasmus, although there was food found post mortem in the intestines. This made him critical of diet and lavage, and drugs he found useless. He rejected the assumption of hyperchlorhydria. Medical treatment should not be too prolonged, as the greater the degree of marasmus the less chance for operation.

Dr. Sutherland said operation was very serious, and many who had undergone it died later from some bowel trouble. The pylorus was an uncertain thing to feel in an infant and the diagnosis could be pretty clear from vomiting, constipation, wasting, and visible peristalsis. If trouble arose with breast-fed infants the fault was with the manner of feeding—not with the milk. Small feeds were required. If a residue was left in the stomach after a day or two of lavage the infant was not having proper food.

Mr. Lockhart Mummery said there could hardly be a more unsuitable subject for a severe operation—a young child, badly nourished, probably having vomited all nutriment for some days before. The prospect was good only before wasting when there was some fat.

Dr. C. W. Chapman put in a word for bismuth carbonate in large doses—a teaspoonful might be given.

Mr. H. Lect said too many cases were hopeless when the surgeon was called in. The physician ought to be clear from the commencement as to how long he would try medical measures, lest the prospects of operation should be too far diminished. He favored gastroenterostomy as simpler than pyloroplasty and safer than Loreta's operation.

Dr. Reginald Miller said the symptoms of stenosis might all be due to spasm. Last year forty cases were collected at the Clinical Society, and in seventy per cent. the onset did not occur till the third or fourth week. Many babies vomited from birth, but not enough to cause wasting, and the constipation was often absent during the first two or three weeks. This seemed as if there was not marked blocking as a congenital lesion. Secondly, only the circular fibers were hypertrophied, and if spasm were the only cause the longitudinal should be also. Thirdly, though the baby did not live, yet as a result of diet and lavage the death was usually due to diarrhea, showing that the pylorus was again patent—presumably the spasm had been relaxed. A fourth controversial point was that some cases had recovered after gastric peristalsis had been seen for weeks and the tumor, too, was palpable. These cases seemed to be identical with those investigated by Dr. Cantley. As to the cause of spasm he thought it might be due to some congenital defect in the gastric juice, but he would not admit hyperchlorhydria. It would be quite an engaging idea if hyperacidity could be considered a cause—a condition seen often enough in babies, but which generally gets well in a few weeks. On the whole he regarded spasm of the pylorus as the cause of all the, if not of the disease, itself

Nutmeg poisoning is not very common here and the literature about it is scanty, but Professor Cushny stated at the Therapeutical Section of the Royal Society of Medicine that on your side Dr. Wallace had investigated it and found the cases all due to the crude nut or to mace. It had been used as an abortifacient, but seems to have no claim to such an action. A case was recorded by Lobelius in 1576 in which a woman became delirious. The death of a boy has been also recorded from eating two nutmegs. The poison is in the oil from which myristicin and some other bodies have been isolated. The symptoms usually noted are drowsiness, diplopia, and delirium. Giddiness is common and, as might be expected, burning pain in the stomach is the first manifestation of local irritation. From experimental work Dr. Cushny concludes that the effects are due to the central nervous system which is depressed, though there may be signs of stimulation, such as restlessness, tremor, and convulsive movements.

Dr. Power said he had been working on the chemistry of the oil, which he found very complex. He isolated much myristicin, which differed a good deal from previous descriptions. The small amount contained in the quantity of nutmeg which set up symptoms suggested a doubt as to whether the poisoning was altogether due to myristicin.

The causation of arteriosclerosis next occupied the section. Prof. W. E. Dixon referred to two theories: (1) Raising blood pressure, (2) toxic influences. He said it had been proved by experiment that the condition could be produced in animals by simply compressing the abdominal aorta for one minute, once or twice a day, and that for a comparatively short period. The changes consisted in a drawing out of the elastic fibers and degeneration of the muscular coat, plaques of calcareous material being formed. This could be brought about in man by very violent exercise, particularly as he grew older, when the rise of blood pressure after exertion was greater than in youth. The effect of nicotine on blood pressure was referred to by Dr. Dixon, who compared the sudden high rise in a young smoker after his first cigar with the slight rise in a moderate smoker and the absence of effect in habitual smokers. He suggested that a ferment which counteracted the nicotine might be produced—probably in the liver.

Prof. Cushny did not think raising the pressure as, for example, by digitalis, would set up in man the changes described by Dr. Dixon in animals.

Votes of thanks were accorded to both Professors Cushny and Dixon for their interesting accounts of their work on these difficult subjects.

Inspector-General Sir John Denis Macdonald, K.C.B., R.N., M.D., F.R.S., died on the 7th inst. in his eighty-second year. He entered the navy as assistant surgeon in 1840, and in 1852 he joined the *Herald* for exploring and surveying service in the Southwest Pacific. In 1850 his scientific work and contributions led to his being elected F.R.S. when only thirty-three years old. From 1870 to 1880 he was Professor of Naval Hygiene at Netty, and from 1883 to 1886 Inspector-General of Hospitals and Fleets. In the last-named year he retired, and in 1902 was created K.C.B.

Surgeon-General Wm. Hy. Rean, M.D., died on the 6th inst. in his eighty-first year. He took M.R.C.S. in 1852 and M.D., S.I., and the following year, after a term as house surgeon at the Middlesex Hospital, he entered the Indian Army, in which he served through the mutiny.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA MEDICAL SOCIETY—A FALSE ALARM OF PLAGUE—NO EVIDENCE OF RAT INFECTION—CHOLERA—REMOVAL OF LEPERS TO CULION.

MANILA, P. I., January 18, 1908.

THE regular monthly meeting of the Manila Medical Society took place in the building of the Philippine Medical School on Malecon Drive at 9 P.M., January 6. No regular papers were read, only a few clinical cases being shown. Among others was a true case of Graves' disease, an authenticated case of which has not heretofore been reported among Filipinos. The principal object of the meeting was the election of officers, and the following were elected for the ensuing year: *President*, Dr. Harry T. Marshall; *Vice-President*, Captain and Assistant Surgeon James M. Phelan, U. S. Army; *Secretary-Treasurer*, P. A. Surgeon Philip Garrison, U. S. N.; *Councillor*, H. D. Kneedler, M.D.

On January 4 a case was encountered in the city which occasioned considerable activity in health circles. In the district of Santa Cruz a Filipino, aged about 18, an employee in an umbrella and hat factory, became suddenly ill

on the morning of January 3. He complained only of severe pains in the chest; no vomiting nor diarrhea was present. No reliable data are available, but from the best information to be had it appears that he had no fever. On the morning of January 4 he died; this was the first time the case came under medical observation. The body was sent to the San Lazaro morgue as a cholera suspect, but upon autopsy the findings common to severe forms of septicemic poisoning were encountered. There were extensive hemorrhages throughout the lungs and upon the serous surfaces of the heart, slight enlargement of the spleen, and considerable free fluid in the abdominal cavity. The intestines showed slight signs of enteritis, but no special pathological changes were noted. The mesenteric glands were considerably enlarged, exuding serum freely upon section. A similar condition likewise obtained in the lymphatic glands of the chest. Smear preparations were made from the glands and stained in the usual way for plague bacilli, and typical bipolar organisms were found. A number of experienced microscopists examined the specimens and all were unanimously of the opinion that the organisms closely resembled those of plague. Cultures were likewise made of the intestinal contents. With a pathological picture that so closely resembled that of plague the Bureau of Health deemed it necessary at once to inaugurate all the modern methods for combating this scourge. The house in which the case occurred was thoroughly disinfected and later treated with petroleum. All textiles were soaked in a bichloride solution, and rat bane and rat traps were placed around the premises, and a general campaign of rat catching was commenced throughout the entire city for the purpose of ascertaining whether the rats of Manila were plague infected. (A limited number of rats are caught weekly in Manila throughout the year and examined for plague, but none have been found infected in nearly two years.) A careful investigation was made of this case from the clinical and epidemiological standpoint, with a result that indicated as closely as an investigation of this kind could that the case was likely not plague. In the meantime the laboratory investigation was continued and within a period of forty-eight hours cultures which had been obtained from the glands grew with typical spore formation, showing almost conclusively that they were not plague bacilli, particularly because the latter do not produce spores, and more time being required for cultures to grow. The diagnosis was still further clarified by an almost pure growth of cholera vibrios being obtained from the cultures which were taken from the intestines. Inoculations into guinea pigs failed to produce plague.

A total of nearly a thousand rats have been caught in various sections of the city since then, and a careful laboratory examination made of them, but so far no plague infection has been found among these rodents. The interesting question now resolves itself into the determining as to just what this organism is that so closely resembles plague bacilli in smear preparations.

Cholera has again made its appearance in more or less virulent form in Manila. Since January 1 there have been 143 cases, with 100 deaths reported. In the provinces there have been 226 cases, with 187 deaths.

The project of the Government to transfer all lepers in the Philippine Islands to Culion has been moving steadily forward. The construction of additional buildings at Culion is now well under way. Among these is included a large camarin of reinforced concrete for the storage of rice and other food stores. The need for such a building was keenly felt in order that the subsistence supplies might be safeguarded against fire. At the end of January there will be accommodations for 1,200 lepers. In November, 148 lepers were transferred from the province of Cebu. This makes a total of 827 lepers transferred from that island to Culion, and it is estimated that there yet remain in that province at least 150 lepers. There were also four lepers taken from Capiz, two from Occidental Negros, and four from Iloilo, who had not been collected at the time the general transfer of lepers from these provinces was made.

Unfortunately, with the last lepers it became necessary to transfer a number who were also afflicted with beriberi. The cases of this disease increased after they reached Culion and a number of deaths resulted, which materially increased the average death rate at the colony.

Health in the Navy.—Surgeon-General Rixey's recent annual report shows that for the past year the total number of deaths in the navy was 241, a ratio of 5.66 per 1,000. Of these only 144 were from disease, the others being due to accidental injuries, including 31 deaths by drowning.

REFORM OF MEDICAL ONOMATOLOGY.

To the Editor of the Medical Record:

Sir:—The editor of the journal, *Salpinx*, of Cyprus, honored me by an invitation to contribute to its jubilee number—the twenty-fifth anniversay of the existence of the journal—and I accepted with pleasure and satisfaction. Presuming that what I said at the occasion may be of interest to all those who have followed my exertions in regard to reform in onomatology, I give here the contents of the article I sent to Cyprus. Whoever has observed how these exertions, the main feature of which was to disseminate a better understanding of Greek history and of the language of Christian Greece among American and German physicans, have been appreciated and encouraged by the *Salpinx* during the past fourteen years, will understand how deeply I am indebted to Mr. Chr. S. Chourmouzios, the editor of that paper.

I wrote as follows: * * * I shall confine myself to one feature which has especially appealed to me when reading the *Salpinx*, viz., the quotations from the writings of Koraïs, the noble son of Greece, the great scholar, patriot, and physician. Koraïs expressed his conviction that no remedy could heal the misfortune of the Greeks but the light of science. From the moment he read his memorial before a learned society in Paris, in 1803, about the condition of his country, in order to direct the eyes of the civilized world to it, he created esteem for the Greek nation. Koraïs has had followers who enlightened Europe on Greek matters; Bikelas gave his seven lectures on the history of modern Greece and the Greek question in Marseilles and Paris. These lectures brought about Philhellenism and the formation of a Philhellenic Society in France. This society had a short life, and so had the Philhellenic Society of Amsterdam, founded and conducted by the indefatigable H. C. Muller. Both societies were composed of distinguished members, and many of the contributions to their organs are of everlasting value; otherwise these two organizations have accomplished little.

The next followers of Koraïs are Hatzidakis and Papademetracopoulos; they have demonstrated to the world of science the true relation of the Greek of to-day to the Greek of ancient times. It is not possible any more that any one can speak of Greek as a dead language, but it should also be made impossible to call Greek spoken and written to-day "New Greek." One thing is certain, that these two men, Hatzidakis and Papademetracopoulos, will be appreciated more and more; they have rendered their country the greatest service by enlightening Europeans on the Greek language and its history. What they have imparted will be disseminated. Applying now what we have learned from them to Greek in medicine, we find that the great problem of reform of medical onomatology, which has vexed so many European scholars for centuries, can be solved in the simplest and easiest manner. What little I have been able to do to direct the attention to the possibility and facility of this solution, I did with the aid of Dr. B. Leonardos, whom I consulted on medical terms, and, in fact, without him I would have accomplished nothing.

On this festive and joyful occasion I wish to introduce all my friends who have stood by me to the readers of *Salpinx*. There is, first, Heinrich Zimmerer, who, a German professor of philology, the philological editor of a medical lexicon, has accepted corrections made with the aid of Greek medical onomatology of to-day. My joy and satisfaction over this fact know no bounds, and I wish long life to my esteemed friend, Professor Zimmerer, and to the celebrated Professor Vierordt, the medical editor of the lexicon. The warmest Philhellen, Colonel Adelbert Boysen, has gained for me in German what I could not obtain in America—access to some important German secular journals. His name is well known in Athens. Dr. Karl Gumpertz, the editor of the *Deutsche medizinische Presse*, has had the courage to publish my articles, by which I attacked deep-rooted prejudices. Dr. Herbert Krüger was my first "secundant" when my writings appeared in the den of the lions, in a Berlin medical journal. Dr. Julius Bartsch, who wrote well-calculated words in behalf of living Greek in medicine in reference to my writings. Inestimably great service has been rendered to the cause by Dr. Eschle, who has taken up the fight for reform in medical onomatology, making the memorial addressed to the rectors of the German universities the base of his writings. In Holland H. C. Muller, the distinguished philologist, has devoted a series of articles in a medical journal of Utrecht to the question, in which he refers to my numerous writings.

Of Americans I wish to praise Dr. D. B. St. John Roosa, who was presiding at the New York Academy of

Medicine when I read my paper on "Greek as International Language of Physicians and Scholars in General," in 1894, and he has stood by me firmly through all the struggles I have gone through these fourteen years, while working for reform of medical onomatology. My sincerest thanks are due to Dr. J. J. Lawrence, the editor and proprietor of the *Medical Brief*, who not only paid me liberally for my contributions on medical onomatology to his journal, but also gave me $1,000 for the new medical lexicon which I intend to write with the aid of my colleagues and friends in Athens. I am keeping this money sacred to apply it when I shall have finished my preparations for the work. How the Greek colleagues have honored me is narrated in the memorial addressed to the German rectors.

Greek in medicine was the theme of my lecture at Johns Hopkins University, and medical Greek has now been the cause that old prejudices are disappearing. I congratulate myself for having succeeded in introducing in Germany a better nomenclature. The starting movement, however, came from America, and the editors, Stedman, who first of all spoke of living Greek in reference to medical language, Foster, Gruhe, and recently Cattell, will forever be named when the history of the reform in onomatology shall be written as the ones who enabled me to carry on the fight, without whose help I would have been helpless. Without my writings, which were published in their journals here in America, I would have received no recognition in Germany.

A. Rose, M.D.

New York.

A NEW FISH FOOD.

To the Editor of the Medical Record:

Sir:—Nowhere else in the United States are economic conditions so pronouncedly elemental as are found in New York City. On the heights full-fed luxury scrambling into a coveted place in "the diamond horseshoe"; in the depths pathetic misery standing in line, craving bare sustenance, with cost of living advancing so rapidly that the workingman's staple diet throughout the year may soon be summed as beer, bread, and potatoes. The present almost prohibitive cost of beef—and cold storage product at that, with its progressive shrinkage in nutritive values from moment of beginning refrigeration—gives to any fresh substitute for meat a peculiar importance. In Italy I find regularly served a fish food which Americans discard through ignorance and prejudice. In the writer's grandfather's day in Philadelphia tomato plants were allowed to exist in the family garden and considered as ornamental, but were never eaten. A fish plenteously distributed up and down our coasts from Maine to Panama throughout the year, and one as palatable as bonita, sturgeon, or halibut, is systematically cast out of the pound-net "fare" at every haul, and thrown away with a malediction by the doryman of the "off sea" fishing smack. Here the finny tribesman finds ready sale at the price of fifteen "soldi" per kilo weight, equal to about eight cents a pound. Anyone who has watched a shark—for it is this fish with which the writer is dealing—romping in a school of "blues" need have no fear that it is not a cleanly feeder. The color of the meat resembles that of the shad, but is of firmer consistency and has comparatively few bones beyond the central spinal column.

At a price of two or three cents a pound tons of these fish varying in size from two to six feet in length could be landed daily at Fulton Market with a fair profit. For a season or two, or until the "corner" manipulator in food staples began his work of price boosting, the fish would prove a worthy addition to the poor man's market basket.

Frederic Griffith, M.D.

Rome, Italy.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 20, 1908.

The Mattapan Day Camp.—D. Townsend gives an excellent description of the work of the Boston Association for the Relief and Control of Tuberculosis at the Mattapan Day Camp. The article is largely statistical and takes up not merely the medical, but also the executive questions suggested by such an institution. The facts he brings out will be of great value to all those who are interested in day-camp work for tuberculosis. The author informs us that the patients come in the morning as early as possible and spend the day in reclining chairs at rest, or indulge in moderate amusements; those who are able are allowed and encouraged to do light work about the camp. In the late afternoon they return to their homes. Patients with a temperature of 100° or above, or a pulse of 120 or above, are placed in one of the rest tents to ensure absolute rest and quiet. Each patient is weighed once a week; this means body weight; the women are weighed with a sheet, 1¾ pound; examined once a month; their pulse and temperature taken twice a day, morning and evening; and the sputum is examined for the presence of tubercle bacilli, as far as practicable, once a month. All these findings are recorded. The throat physician examines all new cases entered previous to his visit and treats all the old cases who need treatment at this time. At 9:30 A.M. a lunch of bread and butter and milk is served; at noon there is a dinner of meat or fish, potatoes, another vegetable, and a wholesome dessert (preferably made of milk and eggs); at 4 P.M. another lunch of milk and bread and butter. When needed eggs are served in addition to the lunches. No medicine is used except symptomatically. The chief aim of the camp is educational.

New York Medical Journal, January 22, 1908.

The Management and Treatment of Tuberculosis in Infants and Children.—J. L. Morse notes that the chief characteristics of tuberculosis in infancy are its malignancy and its tendency to dissemination. The restriction of tuberculosis to a single organ and the involvement of the lungs, as it occurs in later childhood and in adult life, are very unusual. The fatality of tuberculosis at this age is so great, therefore, that little can be hoped from any form of treatment. In young children the tendency to localization is greater. The bones and serous membranes are much more frequently involved than the viscera, and there is also a decided predilection for the lymphatic system. In older children pulmonary lesions are more common, the frequency increasing directly with the age, but they are comparatively rare before puberty. The course of pulmonary tuberculosis at this age is more rapidly progressive than later. At puberty the lesions, course, and treatment are essentially the same as in adults. Children are more rapidly enervated by warm climates than are adults and are not, as a rule, robust to bear extremely cold climates. They accommodate themselves to institution life, however, better than do adults, and after the first few days are almost never homesick. Surgical cases do better at the seashore than inland. The progress of pulmonary disease in early life is worse than in later life. The dietetic treatment is essentially the same as with adults, but greater skill is required to avoid upsetting the digestion. Drug treatment is purely tonic and symptomatic. The children of tuberculous parents should, if possible, be sent away from home. When they cannot be sent away from home much can be done by regulation of their life and by guarding them against infection from the parents. Children suffering from latent tuberculosis or for any reason predisposed to it should, if possible, be given proper climatic treatment or sent to sanatoria. If this is not possible, every attention should be paid to their hygiene, food, rest, and care. The children of the poorer classes should be sent to fresh air schools, and given the advantages of country or seashore air whenever possible.

Precautions To Be Taken in Going South.—Most sensible advice with regard to Southern journeys is given by W. J. Robinson of Florida. Patients should be cautious when arriving at their journey's end, especially if arriving at or just before dark. In the hot climates the temperature may abruptly fall at this hour. Lack of caution in this regard may cause pleurisy or pneumonia. If the traveler is delicate or perhaps convalescent from acute disease, it is an excellent plan to go to bed on arriving, and if hot and perspiring, an alcohol bath and a stimulant would not be amiss. On waking the next morning, if not fully rested and refreshed, it might be just as well to stay in bed during the morning or even the whole day. The fare in the first-class hotels is as good as at the North. Visitors are apt to overindulge in fruit and fish, with the customary indigestion and bowel complaints as a result. The climate presents certain well-defined changes during the day so it is necessary to bring both warm and cool clothing. The author says that he gives to his patients the following advice on this point: "Never change the clothes you have on for lighter ones during the day. Look out of your window in the morning on rising, and if the day is warm and sunny do not fear to put on the thinnest things you have in your trunk and go out. If you find them too thin as the day goes on, then is the time to change to your thicker things again, and you may find them very grateful, for slight changes of temperature are felt much more in hot climates than they are at home." The article avoids discussion of all medical matters and can be very properly placed in the hands of all contemplating a Southern journey.

The Rational Treatment of Iritis.—A. Brav advises the initial clearing out of the gastroenteric canal. Emetics should be avoided. The eye should be placed at rest by atropine or, if it produces poisonous effects, we may use sulphate of duboisine or hydrobromide of scopolamine; if it is necessary to reduce tension, sulphate of eserine. For pain the hot, moist compress gives the greatest relief. Poultices are to be avoided. If morphine is required, it may be combined in the rheumatic cases with the salicylates. Adrenalin is useless and may be harmful. Dionin may be used in combination with cocaine and atropine and while dionin itself (ethyl morphine hydrochloride) does not relieve the pain, it is a useful agent in promoting the absorption of the inflammatory product. Hypopion complicating iritis rarely requires special treatment. Rest, hot compresses, dionin locally, and a cathartic will usually cause the exudate to be absorbed. In rare cases surgical intervention (paracentesis) may be necessary. As to posterior synechia, the ideal treatment is, of course, prevention. A few small adhesions do no or very little harm, and they are, perhaps, better let alone. An effort may be made to break the adhesions by means of a strong mydriatic. Occasionally it is well to contract the pupil first with eserine, followed by a counteraction with a strong solution of atropine. If no success follows this process it is best to discontinue the drugs. It must be remembered that the prolonged administration of atropine may give rise to a secondary glaucoma. Large posterior synechiæ, and especially the annular synechiæ, are dangerous to the eyes, not because they are responsible for the recurrences, but because they eventually destroy the usefulness of the eye by causing a secondary glaucoma. It is advisable to do an iridectomy, although even the surgical procedure is not always crowned with good result. In syphilitic cases the system must, of course, be brought as speedily as possible under the influence of mercury. When the inflammatory symptoms are subsiding the iodide is of great value in promoting the absorption of the inflammatory product. Small doses of mercury should be given even after the eye shows no more signs of inflammation. It is the only safeguard against recurrence. Fresh air, good food, quinine for malarial complications are essential in building up the general state.

Some Unusual Effects of Gonococcus Infection.—W. F. Campbell refers to some of the unusual effects which have been reported by various authors of the gonococcic toxemia. These include cases of diffuse and severe inflammation of the entire upper extremity of one side, gonorrheal pleuritis, arthritic inflammations, pyemia, liver enlargement and icterus, peritonitis (in the male), proctitis, felon, etc. He refers to a personal case of a boy with compound Pott's fracture, which healed under every antiseptic precaution. Four days later pus appeared in the wound and continued to spread up the leg as far as the thigh, requiring extensive incisions about the leg and thigh to secure adequate drainage. Without any reference to the gonococcus, but desiring to find the germ cause of the extensive suppuration, a culture was made from the wound discharge a month after admission and the gonococcus found. It was then discovered that the patient was suffering from gonorrhea, a fact which had not been obtained on his admission to the hospital. He stated that he had acquired the infection three days after being exposed, about six weeks previous to his admission to the hospital. After four months the patient was discharged from the hospital cured with regard to the fracture, but still having slight urethral discharge. In this case infection by direct contact was impossible while the patient was at the hospital, and the cause of the suppuration can only be accounted for in two ways, (a) either the gonococcus circulating in his blood found a point of lowered resistance and there set up a focus, or (b) at the time of the accident the patient may have become inoculated from the germ in question present on his clothing. The author believes that the former supposition is correct.

Journal of the American Medical Association, Feb. 22, 1908.

Operative Treatment of Rectal Cancer.—The operation of dissecting away the bowel in cases of obstructive diseases of the rectum, though preserving the sphincter, and of bringing down the upper end and uniting it to the anus by free cutting of the mesocolon, is discussed by E. Archibald. He reports a case in which it was performed, and which, though unsuccessful so far as saving the patient was concerned, showed that the descending colon with the splenic flexure could be so loosened from its posterior attachments as to be capable of being brought down to the anus without interfering with its blood supply. He reviews the various operations that are or have been chiefly employed for rectal cancer, pointing out their drawbacks, and shows by reasoning and injection experiments on cadavers that it is possible to cut off the whole arterial supply of the descending colon, sigmoid and rectum and still have the circulation maintained as far as the lower end of the sigmoid at least, provided only that the vessels are ligated far back from the bowel so as to leave a broad flange of mesocolon containing the important anastomotic loops of the mesenteric border. He holds, therefore, that the cancerous rectum can be removed in its whole extent from the promontory downward, with the whole territory of the anorectal (Gerota) glands; that the upper segment by employing a proper method of mobilization may be brought down to and through the anal segment without tension and without danger to its blood supply; and, therefore, that the need of making an artificial anus is avoided, save for cases that come to operation during obstruction and the inoperable ones where obstruction threatens and short circulating is impossible, this applying only to cases where the sphincter does not have to be sacrificed. The operation as he would perform it is described in detail and is recommended as the normal procedure for cancers above the anus when the sphincter can be saved. The great advantage is the avoidance of the distressing artificial anus save in inoperable and obstructed cases. The operation being purely abdominal, the pelvic floor is left intact and we may expect normal sphinteric action in all cases. Other advantages claimed are thorough removal of the entire gland-bearing district, greater economy of blood, less cutting of sensory nerves, and less shock and presumably a lower mortality.

Vegetarian Diet in Psoriasis.—The value of a vegetarian diet in psoriasis is urged by L. D. Bulkley, who points out the features of the disorder, indicating it to be due to underlying constitutional conditions and refers to former articles by himself on the subject. It seems to him that the errors of nitrogenous metabolism which are evident in the urinary findings which are constant in psoriasis, must, when prolonged, have their effects on the skin, and, working on this hypothesis for many years, he has become convinced by clinical observation that psoriasis has its foundation in errors in the passage of nitrogenous elements into and out of the body. Bulkley does not advocate confining the treatment exclusively to a vegetable diet, though this is perhaps the most important part. Careful medical supervision in all directions is also required and the use of drugs when called for. He has had his most striking success in the treatment of the disease since he has adopted this plan, and while it has its limitations, and must be intelligently directed, he is confident that in proper cases it can control the eruption and prevent its recurrence.

Atypical Typhoid Fever.—J. P. Bates says that a class of continued fevers is seen in Panama and the southern portion of the United States, and probably also elsewhere, that are too long lasting and resistant to quinine to be malarial and too mild and short-lived in their course to fill the ordinary clinical picture of typhoid fever. He recognizes three groups or varieties of these fevers, the second being the most frequent and important. In the first group there is an irregular fever, lasting about a week, with temperature scarcely above 100° F. and no symptoms except bronchitis and some malaise. In the second group the fever lasts from seven to ten days and may reach 102° F. or more. There may be few or no symptoms, but there are generally headache, bronchitis, and some reddening and coating of the tongue. The patient is willing to keep his bed. In the third group the fever ranges from normal to 100° F., or a little above, and lasts for two weeks or more. In this class there are the usual symptoms of typhoid; there are low muttering delirium, sometimes wild mania, a red pointed tongue, tympanites, and retention of urine. After the close of defervescence there is nearly always a second rise of temperature of varying length and corresponding to the second rise or "*febris carnis*" in the more typical cases. Bates is sure that all these groups are typhoid fever; they occur and increase in numbers with typical typhoid cases, occur in the same houses and surroundings, they frequently relapse, and the relapse may be more severe than the original attack, and they give about the same proportion of positive Widal reactions as the typical cases. Lastly, in two cases affording an autopsy, one dying in a relapse, the other from perforation, the lesions of typhoid were found. These irregular cases afford every facility for the spread of the disease; not being recognized as typhoid they are not reported or controlled by sanitation and, therefore, are a perennial source of infection. He illustrates this by the experience in the Canal Zone. Two hundred cases are briefly analyzed and representatives of each group are reported. He takes up the subject of malaria, pointing out the features differentiating these atypical typhoid cases from malaria and showing from an analysis of 500 cases that malarial fever, if at all amenable to treatment, yields promptly, and lays it down

as a medical axiom that: "A fever which fails to yield to full doses of quinine in five days, although malarial parasites are present in the blood, is not simply and solely malarial fever, and the physician must look further for its cause." When a fever fails to yield to quinine and shows no physical signs or demonstrable bacteriological cause other than malarial parasites, it is, he says, perfectly safe to assume it to be typhoid fever.

The Diagnosis of Appendicitis.—I. C. Chase offers as a useful method for differentiating the pain in appendicitis from that of other conditions simulating it, the sudden and forcible compression of the descending colon in the flaccid abdomen, by pressure on the left lumbar and inguinal regions. The forcing of the gas in the colon backward to the cecum causes a sudden pain in the inflamed area, due to induced peristalsis or movement excited by the sudden cecal distention. He first observed the phenomenon in using abdominal massage for constipation in a patient after an attack of appendicitis, and has repeatedly verified its diagnostic value in real and supposed cases of the disease.

The Lancet, February 15, 1908.

Three Cases of Plague Treated with Yersin's Serum.—Of the cases reported by A. C. Dixon, two recovered and one died, the patients all being natives of Chili. The remedy was injected into the veins, as much as 80 c.c being employed at a dose. The author's experience convinces him (1) that unless the patient has a rigor after the injections the quantity of the serum used has been too small; (2) that the doses usually advised, say 40 c.c., are not nearly large enough for severe cases, and (3) that there is no ill effect from the intravenous injections of the Yersin serum.

The "Early" Operation in Acute Appendicitis.—F. A. Southam presents this subject in tabulated form. Of ten operations done within forty-eight hours all recovered. Of three intermediate operations, done from the third to the fifth day, two recovered and one died. Two late cases, after the fifth day, recovered. All the foregoing were private cases. Of fourteen hospital intermediate cases, seven died, and of fourteen hospital late cases thirteen recovered and only one died. As to indications for early intervention, he notes an early rapidity of the pulse, high temperature, initial rigor, urgent vomiting, acute pain, rigidity of the abdominal wall, and the absence of abdominal respiration. The advantages of surgical interference in the early stage of acute appendicitis are as follows: (1) The infective center—*i.e.* the appendix—can be removed in many cases before suppuration has taken place, and if it has not perforated or become gangrenous, the operation is practically an aseptic one. (2) If pus has formed, even though not encysted and surrounded by a barrier of lymph, it will usually be found to be localized as yet to the neighborhood of the appendix and small in quantity. In these circumstances its evacuation, together with the removal of the appendix, if followed by free drainage, will usually check the spread of the suppuration, which otherwise so often tends to become general. (3) The operation being performed before the onset of general toxemia, the common cause of death in fatal cases, is usually well borne by the patient. (4) The risks of the later complications of acute appendicitis, viz., subphrenic and hepatic abscess, empyema, parotitis, phlebitis, and infections in other parts of the body, are greatly minimized. (5) In the early stage the appendix—unless bound down by adhesions, the result of a previous attack—lies quite free and is therefore easily removable. In the later stages, especially in the less acute cases, it is often surrounded and imbedded in a deposit of lymph, which may form part of the wall of an abscess when the pus is encysted. In these circumstances, it is often not easy to recognize the appendix, and its removal is frequently difficult or impossible without breaking down this barrier of lymph, and thus running the risk of infecting the general peritoneal cavity.

Therapeutic Uses of Normal Serum.—The use of normal serum is commended by E. C. Hart, who has successfully used it in a case of anemia, a second, of tuberculous hemoptysis, a third, of probable gastric ulcer without hemorrhage in a chlorotic young woman, and a fourth of duodenal ulcer with hemorrhage. He believes that oral administration fulfills all indication, and that subcutaneous or intravenous injections are unnecessary. In the above various conditions it is not impossible, he says, that there is a common basis of autocytolysis, characterized by destruction of epithelial, endothelial, hemic or other cells, and that such autolysis can be inhibited by normal serum. Many interesting questions arise in connection with normal serum therapy. For instance, what share have the normal constituents of serum in the results obtained by the use of serums such as the anti-diphtheritic and the polyvalents which we now attribute entirely to the action of abnormally produced bodies? Although the author is optimistic as to the effects of normal serum therapy in various conditions, he says our knowledge of its action is so slight that caution must be exercised in its use, and it is desirable that methods of testing and standardizing the serum with regard to its anti-autolytic, anti-hemorrhagic, and other properties should be employed in the future. It is also important that serum should be used from a horse that has been repeatedly bled, as its activity seems to be thereby enhanced.

Acute Poliomyelitis Associated with a Diplococcal Infection of the Spinal Sac.—The case of a boy of twelve years is reported by W. Pasteur, A. G. Foulerton, and H. MacCormack. At the time of the report the patient was still crippled in the use of his lower limbs. The authors were able to make the following demonstration: Identification of a micrococcus in the spinal fluid withdrawn during life from a patient with symptoms of acute poliomyelitis, success in the production of an ascending motor paralysis in a rabbit after a prolonged period of incubation by inoculating this fluid into the subdural space; the demonstration on the death of the inoculated animal of a micrococcus in the cerebrospinal fluid similar to that seen in the fluid from the human case, and, further, by similarly inoculating another rabbit with an emulsion of cerebrospinal substance and fluid from the first experimental animal, they have succeeded in reproducing a motor paralysis, again after a somewhat prolonged period of incubation, and again associated with the presence of the micrococcus in the spinal fluid. But while they have succeeded thus in obtaining direct evidence of the infective nature of the illness and of its association with a certain microorganism, then evidence is incomplete bacteriologically, since they failed to obtain the micrococcus in culture on artificial media, and so are unable to give a complete description of it. The authors further believe that it has been established that there is a specific infective disease, of which acute poliomyelitis is a frequent and prominent, but not essential, feature. From the scanty information at our disposal it would appear that this specific disease has no clearly distinguishing primary features to enable one to differentiate it by its clinical symptoms from many other febrile conditions of probably infective origin which are frequently met with in practice, but which may not have sufficiently distinctive symptoms to enable a definite diagnosis to be arrived at. And so, whilst the serious complication of acute poliomyelitis when it has occurred has been at once recognized, the primary disease has not been differentiated hitherto, but has, in fact, usually been altogether overlooked.

British Medical Journal, February 15, 1908.

Acute Tuberculous Fever in India.—J. R. Roberts and R. S. Bhandarkar report thirteen cases of this newly recognized malady. During its course, which represents an acute invasion of the tubercle bacillus, the organism is found and continues to be excreted by the urine for a long time. The symptoms are thus described. There is a continued period of pyrexia of a remittent or intermittent type, lasting from a week to four weeks or more; the liver is often enlarged; the spleen not so; the bowels are constipated, generally obstinately. The abdomen shows some amount of meteorism, though this never reaches the extent seen in enteric fever. Vomiting and nausea are marked, though not continuous. The most distinguishing feature of this fever is pain and tenderness in the epigastrium, and it is on this that special stress must be laid in order to assist in the differential diagnosis. Some cases have acute exacerbations of pain, others only tenderness, which, if it be associated with hepatic enlargement, makes the diagnosis from liver abscess very difficult; but the detection of tubercle bacilli in the urine clears up all doubt. The mind is clear, generally remarkably so, except that when the temperature is high there may be some delirium at night. It is interesting to note that patients after recovery give a very clear account of their illness, mentioning the temperatures and symptoms, thus contrasting with the mental confusion of the typhoid state—making the memory of the illness a blank. The initial enlargement of the spleen in enteric contrasts with the want of enlargement in acute tuberculous fever. The tongue is furred, but its condition does not remind one of the "typhoid tongue." The skin is dry and hot; there are no hectic or malarial sweats. The urine is highly colored and contains no albumin. The writers think that this fever is completely recoverable from, and also maintain that it marks the launching of the patient on a tuberculous career. It is the beginning of a long period of ill health of an indefinite kind—dyspepsia of a flatulent type, relapses of fever, periods of general depression with a temperature below normal if frequently and carefully taken, a loss in

weight, and in some cases anemia. This general malaise is not continuous; the condition is varied by periods of good health. Practitioners have been apt to consider this as due to Indian climate and conditions, and recommend a change to Europe or the hills; in fact, just the class of case that does improve under this treatment, and improve immensely, perhaps never to recur. Another set of cases develop obvious tuberculosis—tubercle of the lungs, kidneys, etc. The initial acute tuberculous fever has been long forgotten or has been regarded as malarial. The mortality of the disease referred to is low, and it does not seem to run into the familiar automiliary tuberculosis of European countries.

The Prevention of Tuberculosis.—A. R. Gunn makes a suggestion in regard to procuring a tubercle-free milk. He points that in every community there are certain persons who seem to possess an inborn degree of immunity against tuberculosis which renders them less susceptible to its attacks than their less fortunate fellows. This immunity is transmissible and as time goes on this selective death-rate, which is naturally low among such partially immunes, affects the characters of the race. Now, says the author, if we assume the identity of bovine and human tuberculosis, we should expect to find that among cattle also there are certain individuals who under ordinary circumstances are proof to the disease. The author's proposal, then, is to take these immune individuals and breed from them a strain which would remain absolutely free from any taint of disease. That this is far from being impracticable is demonstrated by the fact that something similar has already been achieved in other forms of life. It has been shown that susceptibility and immunity are definite Mendelian characters, the latter being recessive; and that, by cross-breeding an inferior yet immune type of wheat—immune, that is, to the rust fungus—with a superior yet highly susceptible variety, certain of their offspring are capable of producing a strain which is possessed both of the immunity of the one parent and of the other desirable features of the other. If we can rear a breed of cattle which is practically immune to tuberculous disease, then, by attention to the ordinary requirements of hygienic science as regards cleanliness of housing and cleanliness of milking, the danger from infected food, whether in the shape of meat or milk, to which we are at present subjected, ought to be capable of almost complete removal.

The Treatment of Epidemic Cerebrospinal Fever.—After some observations on the mortality of recent epidemics in different countries, A. G. Robb records his experience with serum in Belfast. Out of 32 patients 22 recovered, 8 died and 2 were still ill at the time of his report. Figures of cases treated at the same time as his own and without serum showed the old high mortality rate, from which he concludes that the type had not become milder and that he personally was not treating unusually mild cases. He presents his results in tabular form and shows several temperature charts. As to dosage, he adopted the following rule: If the case was very severe and especially if pus was found in the fluid obtained by lumbar puncture, to give 30 c.c. or larger doses every day for three days. (In one of our recent cases 70 c.c. were injected within the first twenty hours after admission, with apparently good results.) In cases not so urgent the author thinks it better not to repeat the injection until after a lapse of forty-eight hours. In this way only can the effect of the smaller dose be estimated, as the full effect of a single injection is not always apparent until after forty-eight hours or longer. Some of his results have been very good after a single injection of 30 c.c.; in other cases improvement has only been observed after repeated doses. The largest amount yet given in a single case with us has been 210 c.c. intraspinally. He has not as yet seen any undesirable symptoms follow the use of the serum. In several cases the serum was also injected hypodermically, but in none did any marked effect appear to follow.

Berliner klinische Wochenschrift, February 10, 1908.

Late Infection in Hereditary Syphilis.—Lesser says that the conditions under which the transmission of syphilis from parents to fetus takes place are still somewhat uncertain, and he describes a case in which the infection occurred at an unusually late period in the pregnancy. The parents had been married six or seven years and had four living healthy children. During the fifth pregnancy the husband infected himself with syphilis on February 22. One month later, between March 21 and 25, he had connection with his wife, and on March 26 he for the first time noticed evidences of the chancre. On April 29 the eruption appeared. On May 7 the primary lesion was discovered in the mother and twelve days later the child was born at full term. The child was of normal size and seemed healthy in every way. On June 21 the mother exhibited a plantar and palmar eruption and doubtful traces of a rash could be detected on the body. On July 6 the child was found to have a maculosquamous syphilide and two days later spirochetes were discovered in the secretion of the anal papules. The delivery, therefore, followed between fifty-five and fifty-nine days after the infection and the general lesions of the child appeared on the forty-eighth day. The author thinks that the possibility of an intrapartum or postpartum infection can be excluded and that the case is remarkable for the lateness of the infection and the accuracy with which all the dates could be determined.

The Tuberculin Reactions.—Wolff criticises severely the Pirquet cutaneous tuberculin reaction and the ophthalmo-reaction on the score of their unreliability and the undesirable effects likely to follow the latter. In testing nineteen cases of undoubted tuberculosis by means of the Pirquet reaction negative results were obtained in 36.8 per cent., and in applying the conjunctival test in twenty similar cases negative results were noted in 30 per cent., although all these patients were in the earlier or middle stages of the disease, so that a correct reaction might be expected. In dealing with tuberculous animals the tests were also found unsatisfactory. In comparing these procedures with the old injection method the following results were obtained: In twenty-seven patients suspected of being tubercuIous, of whom seventeen were adults and ten children, the Pirquet reaction was positive in only 59.2 per cent., while the subcutaneous injection was positive in 92.5 per cent. In forty-five similar patients, of whom thirty-six were adults and nine children, the conjunctival reaction was positive in 28.9 per cent., and the subcutaneous injection in 80 per cent. In speaking of the conjunctival reaction he says that although 1 or 2 per cent. old tuberculin solution was employed in a number of cases severe conjunctivitis was caused, sometimes lasting twelve or fourteen days, and so intense as to make it undesirable for the practitioner to run the risk of producing it in his private patients. Taking everything into consideration, he believes that these new methods possess no advantages over the old one of subcutaneous inoculation, while the conjunctival reaction has the additional drawback of sometimes making it impossible to resort to a subsequent tuberculin treatment owing to the recrudescence of the ocular inflammation that follows each injection of tuberculin.

Münchener medizinische Wochenschrift, February 11, 1908.

Immunization by Mouth.—Wolf says that of the diseases which it is possible to influence by methods of immunization, those which, like diphtheria and tetanus, involve chiefly the surface of the body deserve first place, while those having their sites in the gastrointestinal canal, like dysentery, cholera, and typhoid fever are but little susceptible to modification in this way. He describes efforts made to investigate the possibility of immunization by the oral route in such cases and gives the details of experiments in this direction made on mice infected with the bacilli of mouse typhoid. The animals were subjected to a preliminary treatment with paratyphoid bacilli, which were not pathogenic, the method being to administer daily bread soaked in about 5 c.c. of paratyphoid bouillon culture. They were then infected with a culture of virulent mouse typhoid bacilli given in the same way. The immunized animals usually, though not always, showed much greater powers of resistance to the infection than the control animals, the protective process apparently being that, after the infection had taken place, the mice were enabled to produce larger quantities of antibodies than was otherwise the case. The author compares these observations to what occurs in inoculations against typhoid in man, though he does not draw any conclusions concerning the practical solution of this problem.

Experimental Observations on the Action of Bier's Congestion.—Graff describes experiments undertaken with the object of throwing some light on the mode of operation of Bier's method of treating infections by congestion. He says that this action may be purely bactericidal, antitoxic in the sense of neutralizing the substances thrown off by the bacteria, or bactericidal through the intervention of phagocytosis. By testing the effect of congestion serum and edema fluid on the development of colonies of bacteria he arrived at the conclusion that the bactericidal property of these fluids is not the result of simple humoral action. Experiments with tetanus and diphtheria toxin and with strychnine showed that there was no neutralization of the poison, but only a retarding of its action through delay in absorption. Finally, observations with leucocytes and bacteria demonstrated that contact with the congestion fluids stimulated phagocytosis. Whether the good result depends on the presence in the edema fluid of stimulins, opsonins, or bacteriotropins, he is not prepared to say.

Book Reviews.

The Semi-Insane and the Semi-Responsible *(Demifous et Demiresponsables)*. By Joseph Grasset, Professor of Clinical Medicine at the University of Montpellier; National Member of the French Academy of Medicine, and Laureate of the Institute. Authorized American Edition, Translated by Smith Ely Jelliffe, M.D., Ph.D., Clinical Professor of Mental Diseases, Fordham University N. Y.; Visiting Neurologist, City Hospital, New York. New York and London: Funk & Wagnalls Company, 1907.

Most practical alienists are willing to concede that there are occasional individuals, met with in medicolegal work, who are difficult to classify either as insane, and therefore totally irresponsible, or sane and therefore entirely responsible. Few, however, will concede that these individuals constitute a group of sufficient magnitude to warrant a third classification into semi-insane and therefore semi-responsible criminals. The dangers of such a classification are too numerous and great, and opportunities for court-trial quibbling over criminal responsibility, already unendurable, would, if we accepted it, be still further enhanced. The semi-insane should be grouped among the insane and other terms employed to embrace Grasset's cases. The employment of such a term as "semi-insane," from a legal point of view, seems unsafe; and from a medical viewpoint, uncertain, unsound, and unscientific. With this protest against the title of the book, we may say that the work is excellently translated, and presented in a delightful way. The author maintains that the semi-insane and semi-responsible have both a scientific and a legal right to existence. He first depicts them as they appear in literature and on the stage; then describes them clinically as he sees them in daily life. He differentiates those who have shown talent or even genius and whose lives have been of real social value, and who yet have been what he calls semi-insane, from those who have been pernicious to society and a source of danger. The medical idea of social responsibility is next taken up; and finally are considered the question of diminished responsibility and the general principles of social prophylaxis for the "semi-insane."

Practical Anesthetics. By H. Edmund G. Boyle, M.R.C.S., L.R.C.P., Assistant Anesthetist to St. Bartholomew's Hospital, Demonstrator of Anesthetics to the Medical School of St. Bartholomew's Hospital, Late Senior Honorary Anesthetist to the Paddington Green Children's Hospital, Senior and Junior Resident Administrator of Anesthetics at St. Bartholomew's Hospital. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1907.

In this small volume the author has endeavored to treat of the administration of anesthetics in a practical manner, and discusses, in order, Nitrous Oxide, Ether, Chloroform, Ethyl Chloride, and Mixtures and Sequences. In speaking of the advantages of the gas and ether sequence, the author says: "1. It is the safest method of inducing anesthesia for major operations that we at present possess. 2. Unconsciousness is rapidly produced, and if the anesthetic is properly given there should be few, if any, unpleasant sensations during its administration." Dr. Boyle, however, takes the position that ether is not the most suitable for maintaining anesthesia and should not be given for longer than a half to three-quarters of an hour; after that period the anesthetic should be changed to chloroform.

Medical Ethics: A Guide to Professional Conduct. By Robert Saundby, M.D., Edin., etc. Second edition, enlarged and rewritten. Philadelphia: J. B. Lippincott Company, 1907.

Books on Medical Ethics are few, and as a rule do not make interesting reading. Unfortunately, those who most need instruction on this subject are beyond the reach of books, medical societies, or anything else. The present volume is intended for the instruction of students and young practitioners; and, though written for the profession in England, it will prove useful to readers on this side of the Atlantic who need its instructions.

Surgical Emergencies. By Percy Sargent, M.A., M.B., B.C. (Cantab.), F.R.C.S., Surgeon to Out-Patients, St. Thomas's Hospital; Assistant Surgeon to the National Hospital for the Paralyzed and Epileptic, Queen Square, and Surgeon to the Victoria Hospital for Children, Chelsea. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1907.

This is a useful book for the student and for the physician who has not had the advantage of a surgical training. As the author says in his preface, the book lays no claim to completeness; it is rather of the nature of an essay based upon an experience gained during some eight years' intimate association with the surgical side of St. Thomas's Hospital. The author has covered practically all of the surgical emergencies that are met with in practice. Under the head of "Acute Infective Diseases" the different diseases caused by the pus forming bacteria, tetanus, and anthrax, are discussed. In the chapters on "Acute Abdominal Diseases," and "Injuries to the Abdomen," much stress is laid upon the importance of the diagnosis of peritonitis and the indications for operation.

A Reference Hand-Book of Obstetric Nursing. By W. Reynolds Wilson, M.D., Visiting Physician to the Philadelphia Lying-in Charity; Member of the American Pediatric Society, etc. Illustrated. Philadelphia and London: W. B. Saunders Company, 1907.

This book is intended by the author for the instruction of nurses who have had no practical training in the subject, and are yet desirous of undertaking obstetrical work. Fortunately, the book will be of little service to these nurses, for obstetrics is a subject which can be learned only by practical work. Certainly no nurse will become capable of undertaking a case of labor if her knowledge is derived solely from a perusal of this volume. Those who have had a proper training will not need the book.

A Manual of the Practice of Medicine. Prepared especially for Students. By A. A. Stevens, A.M., M.D., Professor of Therapeutics and Clinical Medicine in the Woman's Medical College of Pennsylvania; Lecturer on Physical Diagnosis in the University of Pennsylvania; Physician to the Episcopal Hospital and to St. Agnes's Hospital, Assistant Physician to the Philadelphia Hospital; Fellow of the College of Physicians of Philadelphia, etc. Eighth edition, revised. Illustrated. Philadelphia and London: W. B. Saunders Company, 1907.

This book is merely an outline of the practice of medicine, and is intended as a manual for students. The statements made are concise, so much so that many times the true meaning is shrouded in obscurity. Prescriptions are freely scattered throughout the book. As a rule each disease is treated under the several heads: definition, etiology, pathology, symptoms, diagnosis, prognosis, and treatment. Such a condensed treatise, however, in the hands of the general practitioner is of little value.

A Text-Book of Pathology, with an Introductory Section in Post-Mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., Emeritus Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York, and T. Mitchell Prudden, M.D., LL.D., Professor of Pathology and Director of the Department of Pathology, College of Physicians and Surgeons, Columbia University, New York. Eighth edition, with thirteen full page plates and six hundred and fifty illustrations in the text in black and colors. New York: William Wood and Company, 1907.

In commenting on the appearance of the eighth edition of a book so widely known as the present it would border on presumption for the reviewer to attempt to point out its excellencies. That these have been universally recognized is demonstrated far more clearly by the demand that has made such frequent reissues necessary than would be possible by any enumeration of the many particulars in which it surpasses all other similar works and which render it *facile princeps* among the treatises on pathology in the English language. The revision of the present issue has been painstaking thorough and there is hardly a section that has not been judiciously pruned or amplified. Naturally all of the recent advances, such as those concerning the opsonins, the spirochetes in syphilis and other conditions, the demonstrations of the Negri bodies, the etiology of smallpox, the transplantation of tumors, etc., receive authoritative discussion, while entire new chapters, such as the very beautifully illustrated one on malformations and the one on the conditions of disease in general, contribute to the one hundred and seventy-five pages by which the letter press has been increased. The illustrations have always been a noteworthy feature of the book, but over a hundred new ones appear in this edition, many of them showing extremely rare conditions rendered available only through the unusual facilities for obtaining material at the disposal of the author, the latter term being used advisedly, since Professor Delafield no longer shares in the work, and Professor Prudden has assumed full responsibility for this revision as for its two predecessors. Especial mention should also be made of the completeness with which important contributions to the literature of the different subjects have been noted, making the volume a veritable mine of bibliographical information of the greatest value. The work is indeed a masterpiece of which American pathology may well be proud.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 6, 1908.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Obstetrics and Gynecology. The subject for the evening was "A Review of Recent Advances in Obstetrics and Gynecology."

The Present Significance of Chorioepithelioma.—Dr. James Ewing presented this communication. The conclusion he reached was that chorioepithelioma included three rather distinct types of tumors, distinguished by their gross appearances, histological structure, prognosis, and indications for treatment. Marchand in 1895 pointed out that these tumors were of two types, the typical and the atypical, and this division had been generally recognized. The typical chorioma of Marchand showed extreme variation in structure and clinical course, and while some proved very malignant Schlagenhaufer in 1899 had pointed out that recovery might follow after spontaneous extrusion of the tumor from the uterus, removal by curettage, or partial removal by knife, a part of the tumor having been left in the pelvis. At least six cases were on record in which recovery followed where pulmonary metastases were believed to have occurred, although the existence of genuine metastases, while probable, had never been proven. On the other hand, some of the tumors were excessively malignant and with them the results of operation were so bad that a recent writer, Schmauch, stated that it was a crime to remove the uterus in such cases. It seemed to be time that a further attempt be made to subdivide these tumors on their structure, and to determine if a given structure did not carry with it a definite prognosis. The speaker's cases seemed to show that such a relation actually existed with the different forms of chorioma, and the following classification and nomenclature was suggested:

Syncytioma; Atypical Chorioma of Marchand.—This tumor produced more or less diffuse infiltration of the myometrium, or a large intrauterine tumor, leading to marked enlargement of the uterus, but not tending to penetrate the organ and not giving metastases. The tumor was composed of large syncytial wandering cells in the walls of the sinuses and in the musculature. Hemorrhage, cachexia, suppuration, and perforation by the curette might prove fatal. Curettage cured in the early stages.

Chorioadenoma Destruens; Malignant Placental Polyp.—This tumor tended to infiltrate the uterine sinuses, enlarging that organ, but not splitting it by a compact growth. Metastases occurred in the lungs and vagina, but recovery might follow. The growth showed villi, Langhans' cells, and syncytium. Hence, as the placenta was a gland, the term adenoma was applied to this tumor. The natural course was death by hemorrhage and cachexia. The uterus should be removed, unless the growth was attacked early and the loss of the organ was a serious consideration to the patient. Spontaneous extrusion, curettage, and partial removal had cured.

Choriocarcinoma.—This tumor produced a relatively small circumscribed growth in the musculature, tended rapidly to perforate the uterus without greatly enlarging it, and to cause local and pulmonary metastases. Villi were absent, Langhans' cells and syncytium were present in masses, but often were imperfectly differentiated. Morphological signs of anaplasia and malignancy were always present. Tumors of this structure were probably always fatal. The different types of these tumors were illustrated by lantern slides.

Recent Advances in Obstetrics.—Dr. Edwin B. Cragin read this paper. He said the advance in obstetrics had been most marked along three lines, a better knowledge of obstetric pathology, a better knowledge of the mechanical problems of delivery, and better procedure.

Obstetric Pathology.—Distinct advance had been made in the toxemia of pregnancy, as evidenced by pernicious vomiting on the one hand and eclampsia on the other. The pernicious vomiting of pregnancy was a toxemia with distinct pathological lesions and with characteristic urinary findings. The chief pathological lesion was a fatty and hydropic degeneration of the liver which was apt to be diffuse, but in some cases was zonal and went on to necrosis. If the condition had existed for some time the lesions found were practically identical with those of acute yellow atrophy. The kidneys showed more or less degeneration of the epithelium of the convoluted tubules. In the urine were found acetone, diacetic acid, β-oxybutyric acid, indican, perhaps a trace of albumin, and a few casts and bile pigment. There was also an abnormal nitrogen ratio. Cases of pernicious vomiting had shown, as a rule, a high ammonia nitrogen, high amido acids, and undetermined nitrogen, and a low urea nitrogen. Clinically he recognized two types of cases, the hepatic and the nephritic. In the former, aside from the convulsions, there were vomiting, with little edema, little albumin, and few casts; there often were jaundice, tenderness over the liver, and tympanites. In the nephritic type there were headaches, disturbances of vision, high tension pulse, nervous irritability, edema, marked albuminuria, and casts. These two types were often combined. In the livers studied by Dr. Cragin there were three varieties of lesions: (1) In the nephritic type the cells near the periphery of the liver showed a moderate fatty and hydropic degeneration without necrosis, while the cells in the center of the lobule seemed normal. (2) In the case of the hepatic type the fatty and hydropic degeneration at the periphery of the lobules was very marked, the cells had lost their nuclei, and, in fact, they were necrosed cells and the most important lesion. There was a necrosis at the center of the lobule, a zone of fatty and hydropic degeneration near the periphery, and a few normal cells at the periphery along the portal vessels. (3) In this there was an area of degeneration of the liver cells with hemorrhage, the so-called hemorrhagic hepatitis. The lesion was situated at the periphery of the lobule. In many cases of the hepatic type thromboses were seen in the vessels at the periphery of the lobules. In eclampsia the myocardium often showed degeneration, and the brain edema and hemorrhages, but these were less characteristic than the lesions in the liver and kidneys. In the nephritic type of eclampsia two classes were recognized: 1. Those who had previously suffered with nephritis and in whom the eclampsia had developed an acute exacerbation of the old trouble. 2. Those whose kidneys had been previously free from disease. There was a marked resemblance between the hepatic type of eclampsia and the pernicious vomiting of early pregnancy, *i.e.* ammonia nitrogen, amido acids, and undetermined nitrogen were above normal, and urea nitrogen was below normal. As the knowledge of the vomiting of pregnancy had increased, the fact had become more and more impressed that while in the early months one might recognize vomiting as either toxemic or reflex, the pernicious vomiting of the early months and all vomiting of the later months was certainly toxemic. Advances had also been made in their knowledge of the pathology of chorioepithelioma and of puerperal infection.

Better Knowledge of the Mechanical Problem of Delivery.—One of the greatest advances in practical obstetrics had been the study of the relative size of

the fetal head and the pelvic canal during the latter weeks of pregnancy. Another advance was in the early recognition of posterior positions of the vertex and the relatively early anterior rotation of the occiput by the obstetrician when nature failed to accomplish this. The proper correction of this malposition implied careful watching of the fetal heart during labor, the cephalic application of the forceps as distinguished from the pelvic, and the use of the forceps as a rotator.

Better Procedure.—This was based upon the two preceding divisions of his paper. In the pernicious vomiting cases one did not feel that he had done his duty by his patient unless the urine had been examined and the nitrogen partition determined and the presence or absence of acetone, diacetic acid, etc., ascertained. No one of the laboratory findings or groups of findings could be relied upon exclusively for prognosis or indications for treatment. It was only when they were studied in connection with the clinical picture that their decision could be made. In pernicious vomiting of pregnancy the best results were obtained by colon irrigations, rectal feeding for a short time only, and early emptying the uterus. Recent knowledge of chorioepithelioma demonstrated well the fact that prolonged menorrhagia and metrorrhagia following labor, abortion, or operation for hydatidiform mole should be looked on with suspicion, and that early diagnosis and early hysterectomy alone gave hope of satisfactory results. In the treatment of puerperal infection the knowledge of the ease of the spread of infection had brought about one improvement in procedure, viz., the rule to keep out of the uterus unless it contained material which should be removed; if the removal of any material was indicated, it should be done with the least possible injury to the uterine wall so as to avoid opening new avenues of infection. The induction of labor two weeks before term would often secure a relatively easy and safe birth for a child which otherwise would be lost. The improved methods of inducing labor at the proper time for the child to pass the given pelvis and the low mortality of cesarean section had largely reduced the number of cases in which craniotomy was considered justifiable. The operation of pubiotomy was still *sub judice,* and would probably never have a large field in private practice; but in hospital practice it gave promise of saving children which would otherwise be lost. With regard to the treatment of lacerated cervices Dr. Cragin believed that in proper surroundings with good light and proper assistance a well trained man might repair a laceration of the cervix immediately after labor; but he wished to sound a note of warning that without the above conditions the morbidity, if not the mortality, of the patient was markedly increased, and for the general practitioner the safer rule was the old one, immediate trachelorrhaphy for hemorrhage only.

Progress in Gynecology.—Dr. Herman J. Boldt said that not so many years ago it was not an uncommon occurrence for an operator to exhibit uterine appendages that were practically normal as trophies of his skill. This showed that the indications for operation were then based upon poor judgment. Following this period of indiscriminate extirpation of the pelvic organs came a period of ultraconservatism, which had the advantage that the radical operation might be subsequently done. Greater conservatism was exemplified in operating for tubal pregnancies, and some now removed the tube only, retaining the ovary. Under favorable circumstances some operators contented themselves with splitting the affected tube and removing the conception product. Most operators were agreed on this kind of conservatism of the pelvic organs, but not so in conservative operations for multiple myomata. With pedunculated tumors and single interstitial tumors of moderate size, they could do a myomectomy with safety. Myomatous tumors were not so innocent as formerly believed. They were now operating more radically upon uterine carcinoma, exsecting the parametria and the glands, and even part of the ureter in some cases. Marked progress had been made in chorioepithelioma and in the purulent peritonitis. After removing the primary cause of the peritonitis no further attempt should be made to rid the abdominal cavity of the purulent secretion by sponging and flushing, because the time consumed was too long and traumatism was too great. One should be contented to drain the cul-de-sac. Rapid work was essential. The patient should be placed in bed in a semi-sitting posture and continuous instillations of saline solution used. To cure a patient of a rectocele it was necessary to separate the bladder from its cervical attachment and displace it upward and then attach the vagina to that part of the cervix to which the bladder had been previously attached.

The Practical Application of Our Recent Knowledge in Obstetrics.—Dr. Edward Reynolds of Boston read this paper. He said the methods of practice which he wished to present were based upon the beliefs that the mortality of cesarean section varied so greatly in accordance with the period of labor at which it was performed that (1) the mortality of the section late in labor was too great to permit of its performance in the interests of the child alone; (2) the maternal mortality of the section performed even so early as the end of the first stage of labor was greater than that of the ordinary high forceps or version; (3) the mortality of the section done at the time of election in advance of labor, or at its very beginning, the primary section, was so low that it was a safer operation for both patients than difficult forceps or version when performed for mechanical obstacles. His own experience with section now comprised thirty cases, all without mortality. He divided the cases into those done before labor (primary), early in labor (secondary), and late in labor (late sections). His completed tables contained 289 cases operated upon by twenty different operators; of these 82 were primary, 158 secondary, and 49 late. The mortality was 12 per cent. in the late cases, 4 per cent. in the secondary cases, and slightly over 1 per cent. in the primary cases. His proposition was: First, that a section undertaken under every surgical advantage in advance of labor was less dangerous than after a few hours' endurance of the exhausting physiology of labor, and under the technical conditions incident to such work. Second, that the section performed after a full test of labor had demonstrated the approaching failure of the natural forces was an operation favorable to the child, but more dangerous to the mother than the intrapelvic methods of extracting by high forceps or version. There could be no plainer or more obvious deduction than that when the cesarean section was necessary, it was desirable that it should be determined in advance and performed as a primary operation. The results of the primary section when performed on healthy women for merely mechanical obstacles were the highest possible degree of safety for the child, a maternal mortality risk which was probably not greater than that of difficult high forceps or version, and an entire absence of the extensive vaginal trauma, and consequent morbidity, a percentage of which they knew to be inseparable from the difficult intrapelvic operations. The secondary cesarean section had a considerable maternal mortality, and, therefore, he ruled out the performance of the secondary section as an operation of choice. The mistakes in the past had been due chiefly

to an over-dependence on measurements of the pelvis alone and to over-confident attempts to determine this important question at a single sitting. To obtain really accurate results they should estimate with equal care the pelvis, the passenger, and the probable maternal power as a propelling engine; to obtain any just estimate of one of these in difficult cases it was usually necessary to see the patient repeatedly during pregnancy, and when it was possible before pregnancy. The whole matter of the estimation of the shape of the pelvis was as yet in its infancy. The fault in the past management of cesarean section had been that they had too often adopted or refused it without sufficiently painstaking observation, and also without a full recognition of the superior safety of the primary operation. The general practitioner should be taught that in difficult labors no obstetrician, however skillful, could obtain a low percentage of mortality, fetal or maternal, if he was only called in after arrest had occurred. All primiparæ should be examined for determination of the mechanical conditions during pregnancy. (1) All primiparæ of small stature; in this type of woman they found the symmetrically small pelvis, the pelvis nana. (2) All primiparæ who had done heavy muscular work during the period of development, and more especially all of those who presented a squat, short-legged appearance; in these women were found the flat pelves. (3) All primiparæ with the narrow hips, long, straight-legged, flat-backed, boyish type of figure; in this type of women they found the true justo-minor or neutral type of pelvis. (4) All primiparæ with bandy legs, protuberant buttocks, prominent abdomen, an unusually hollow lumbar region; such women were often rather wide-hipped, markedly feminine in figure, and at first might suggest favorable labor; but in these there were mostly found pelves with excessive inclination of the brim and exaggerated curvature of the pelvic axis. (5) All primiparæ of delicate general health; many of these women had easy labors but in them even moderate mechanical difficulties assumed importance. (6) Multiparæ who had had easy labors demanded no special care, but all multiparæ who had had even one difficult or disastrous labor should have a determination of the mechanical conditions during pregnancy. It was a fact that twenty-five years ago the care of normal labor by practitioners who were otherwise well equipped was frequently so poor as to furnish a basis for the position that all labor should be attended by specialists, but this was not the case to-day. With the advent of asepsis and general advancement in professional equipment and sense of responsibility for results, the average of obstetric practice had risen greatly, and there were to-day great numbers of practitioners who were quite sufficiently equipped for the intelligent care of an ordinary labor, and for the performance of ordinary obstetric operations. They ought to recognize this change. As in other specialties, the conditions of practice had taught the necessity of not absorbing the management of cases which were referred to them merely for an opinion. If the obstetrics of the future was, as he believed, to assume a more desirable position as a specialty than it had ever before, it would be in part because of the change that was coming over their methods of practice, and in part because its practitioners would find themselves not only forced but glad to assume the position characteristic of all other specialties, *i.e.* those younger obstetricians who desired to take charge of normal labor, and he thought that established specialists would in the future decline normal labors.

Dr. William M. Polk laid stress upon the necessity of a very close watch upon every woman whose uterus had not undergone proper involution, and every man who practised obstetrics should look into this. He regretted that more had not been said in regard to the slow forceps delivery; there had never been anything so potent for good as the obstetric forceps, but they all realized that in them danger lurked, for they were capable of doing damage which was not limited to the external parts—apart from the dangers of sepsis and lacerations—but they were responsible for a great number of cases of procidentia. The fact that a forceps delivery could be extended over an hour or even longer until such a time as the uterus could be coaxed into action, made this worthy of their earnest consideration. He agreed with what had been stated in regard to the early and late repair of lacerated cervices. The disorders of menstruation in young women were very frequently the groundwork of many of those after-conditions, such as diseased ovaries, which ultimately led to those wretched cases of neuroses which revolved around ovarian pain. Many women began the function of menstruation under conditions far from hygienic, and carried on this function under conditions of ignorance as to its true significance; true pathological conditions laid in girlhood formed the groundwork of subsequent ailments. He wished to emphasize the vast advantage of early and prompt incision and drainage in the lower portion of the pelvis, or cul-de-sac, in those cases of pelvic peritonitis associated with septic infection of the uterus.

Dr. Clifton Edgar said he was grateful to Dr. Cragin for bringing out the value of the nitrogen ratios as diagnostic factors. The same value was not now given by some to this method of examination of the urine as was given two or three years ago. It had been belittled by some. A line to-day could be more sharply drawn than ever before between the pure nephritic and hepatic types of eclampsia. While he took into account the clinical picture in conjunction with the urinary findings, still there was a small class of cases in which the urinary findings often flew the red flag, giving out the danger before the clinical condition and picture was particularly well marked. He had a number of such cases that he expected to report next autumn. Sometimes one saw a combination of these two types. With regard to the immediate repair of the cervix after labor, this should only be done in those cases in which there was hemorrhage. The keynote of both the obstetric papers was prophylactic obstetrics. It was Utopian to believe that they had arrived at a condition of affairs where dystocia would be prevented weeks before labor set in. While they had obtained an admirable condition of affairs in institution work, this was not so in private practice. The mortality from puerperal sepsis was one-tenth of one per cent. or less in institution work, while in private practice the mortality was large. The reason for this diminution in the mortality and morbidity rate in institutions was due to the introduction of asepsis and antisepsis in midwifery. The inference was plain. In institution work the morbidity and loss of sight was practically nil; in private practice in New York State in 1906, 26 per cent of the cases of blindness were found to be due to ophthalmia neonatorum. Examinations in pregnancy, especially in the primagravida, were of value in determining contracted pelves and large children; this was carried on in institutions but not in private work. In speaking of the advances in midwifery he referred to a box on the table before the Academy, the property of the late Dr. Bedford, who died in his sixty-fourth year, in 1870 or thereabouts. The top tray contained eleven instruments; of these eleven, ten were designed to mutilate the child, or break it up, and only one was for the delivery of a living child.

Dr. Charles Jewett said that in the toxemias of pregnancy the general condition of the patient must still remain the principal guide in the treatment. The nitrogen partition, however, was of great value and especi-

ally in cases in which the indication for interference was not entirely clear from the clinical standpoint. Eclampsia sometimes occurred explosively with scant clinical premonition. The end might come unexpectedly in pernicious vomiting. Could an elaborate analysis of the urine be made at short intervals in all cases of pregnancy vomiting and in all pregnancies in the later weeks or months, many lives might be saved. Objections had been made against the nitrogen coefficient because an increase in the proportion of ammonia nitrogen might be due to starvation rather than to pregnancy toxemia. Pubic section had a limited field, and had grown more so with the improvements in the status of cesarean section. During labor they had a place in obstetric surgery for certain cases in which the condition of the patient was such as to forbid cesarean section. The cesarean operation was suited to any degree of contraction, and it alone effected delivery and without traumatism to the cervix. The most serious feature of pubic section, however, was the prolonged and difficult after-care of the patient. It was claimed that the mortality of pubiotomy was slightly less than that of symphyseotomy. Yet in many instances after hebotomy the women had been more or less crippled owing to thrombosis and septic complications that developed in the crural veins. The principal objections to the immediate suturing of a lacerated cervix was the danger of sepsis. The cervix was perhaps the seat of less resistance than other parts of the birth canal because of the trauma it suffered even in spontaneous delivery. The cervix should not be immediately sutured after delivery except when necessary for hemostasis.

Dr. George L. Brodhead said that while the two types of toxemias of pregnancy, the nephritic and hepatic, might be combined, as a rule, most cases could be classed as renal and hepatic. The time had not yet come when they could state that because the nitrogen partition did not show a proper amount of ammonia, urea, and undetermined nitrogen, or because acetone or diacetic acid was present, that the uterus should be emptied. The clinical picture must be taken into account as well as the urinary findings. Now and then one met with a pelvis that was perfectly normal in its external measurements, but which was nevertheless contracted. Many obstetricians rotated the occiput forward as a routine practice and had done so for years in occiput posterior cases. Great advances had been made in the more frequent use of craniotomy both in vertex and breech cases when the child was dead. The cervix should be sutured immediately after delivery only in cases of cervical hemorrhage. He believed that one might be tempted to do cesarean section too often; many patients could be delivered at the eighth month safely and the child would do well. When cesarean section had been done there was always the danger in subsequent labors of rupture of the uterus at the site of the scar. Many of these ruptures had been reported.

Dr. F. A. Dorman emphasized the importance of the clinical evidences of toxemia, those that were often overlooked by the general practitioner. Every man should watch the case closely and investigate the excretory and digestive functions, the circulatory system, the nervous manifestations, neuralgic or mental. In prophylaxis the use of the rubber gloves should be emphasized. There was still a large field for the induction of premature labor. He asked Dr. Cragin in what class of cases he thought the vaginal cesarean section was indicated and what were the results. He asked Dr. Reynolds wherein he considered the danger of cesarean section increased by the test of the first stage if the patient was in careful hands.

Dr. W. Gill Wylie said that in his practice of over twenty-five years he had made a close study of all these cases from the very beginning, and it was amazing how often cases of toxemia and septic troubles in obstetrics might be avoided. The prevention of disease would show the greatest advance in the future.

Dr. James Ewing, in speaking of the nitrogen partition, said that this method was presented as one which might give information of value but it was not intended to supersede other and older methods. It was not intended to tell when to empty the uterus; it only told when metabolism was not right. Disturbed metabolism then would be the object of treatment. The nitrogen partition, therefore, should not be taken to indicate the time any more than the method of emptying the uterus, but rather it should be used as a basis of treatment to prevent the necessity of emptying the uterus.

Dr. Edwin B. Cragin, in answer to Dr. Dorman's question, said that personally he believed the elective vaginal cesarean section had but a small field. There were certain cases in which one believed he could dilate the cervix sufficiently to deliver the child, but the cervix would be too hard and unyielding, and in such cases the vaginal cesarean section would prove of great value.

Dr. Herman J. Boldt said that the adenomatous type of chorioepithelioma might sometimes be as dangerous to life as the carcinomatous type. In his opinion it was in the best interests of the patient to do radical work on the basis that they were dealing with a malignant form of disease.

Dr. Edward Reynolds of Boston closed the discussion. He said that he did not think that at present it was generally realized how much the mortality of cesarean section was raised in proportion to the length of labor. This was a matter he had watched for fifteen years and in the literature of the world he had never seen an exception to the rule that when any considerable list of cases was analyzed its main mortality was found among the late cases. In answer to Dr. Dorman's question, he said he did not think they were able to give an answer which would be authoritative or satisfactory in a scientific sense; perhaps the best hint at an answer was to propound another question. If a hundred strong young fellows started on a twenty-five-mile Marathon run, and a certain proportion of them were pulled out at the end of each mile, and subjected to a simple abdominal operation, such as an appendectomy, would not any surgeon expect that the mortality among those operated on in the full flush of condition at the start would be less than among those who submitted to it as they came struggling in at the finish? Would it not be, in general, roughly proportional to the amount of exhaustion which had preceded the operation?

SECTION ON GENITOURINARY DISEASES.

Stated Meeting, Held November 20, 1907.

Dr. Martin W. Ware, Chairman, Pro Tem.

Nephrectomy for Right Pyelonephritis.—Dr. Tilden Brown reported the case of a married woman, 33 years old, who was admitted to the Presbyterian Hospital on August 13, 1907. She had never had children, and her family history was negative. During the past summer she had had repeated attacks of nausea of brief duration. Ten days before admission, without assignable cause, the patient noticed that micturition was painful and that the urine was tinged with blood. Twenty-four hours later she had a sudden attack of pain in the right lumbar region; this occurred during the night, the pain seeming to radiate in all directions and increase in severity. There was no nausea nor vomiting. A hot-water bag gave some relief, and on the fourth day the patient was up again, feeling fairly well. On the following day she had chills, followed by perspiration and fever, and on the three fol-

lowing days she had four or five attacks of pain in the right lumbar region, similar in character to the first one. Micturition was still accompanied by burning and smarting, but stoppage was only noted on the first day. No history of any stone having been passed or found in the urine. When the patient entered the hospital her chief complaints were pain in the right lumbar region, somewhat painful and frequent micturition, fever and weakness. She looked sick. In the right side, beneath the costal margin a roundish, painful, and moderately movable oval mass was easily felt. It was clearly the right kidney or kidney plus something encompassing it. A synchronous catheterization of both ureters was made. The cystoscope showed nothing abnormal to excite the least suspicion about either ureter opening. The urinous excretion from the right kidney was one-third more rapid than from the left. The naked-eye appearance of both urines was nearly the same and nearly normal. Microscopical examination, however, made of drops direct from the catheter, showed pus and bacteria in the right kidney. While there were no abnormal elements seen in the left kidney urine, cultures made at the same time of urine from each kidney showed the following day in the right side cultures, very numerous colonies of a pure growth of the colon bacillus, while one culture from the left kidney showed very few colonies of the same organism. Temperature on admission and on the following day before operation was between 102° and 103°. The day after operation the temperature was between 100° and 101°. On the fifth day it had become normal. The day of operation, August 14, blood examination gave 25,700 white cells. Upon oblique lumboabdominal retroperitoneal exposure, the prolapsed enlarged kidney was found within a normal fatty capsule. Even through the fibrous capsule the surface was seen closely studded with slightly raised bean-sized lesions of different darkish shades. The picture was intensified on stripping the fibrous capsule. The infectious foci were so numerous and often confluent that, taken in connection with the clinical history, the indications for nephrectomy were not doubted, and the operation proceeded with. The immediate postoperative state was gratifying; fall of temperature, absence of pain and competent action of the other kidney occurred. There was no infection of the wound cavity, and its cutaneous layer was closed in a week. Twice during her convalescence there were local and systemic signs, suggesting possible trouble in the left kidney. These disappeared, and she is now, three months after operation, in excellent health and strength. The pathologist reported that the kidney measured 11x7x5 cm. and presented the usual appearance of pyelonephritis, except that the purulent infiltration has not yet caused softening. Microscopical examination showed numerous scattered patches of purulent inflammation. This finding explained why the urine from this kidney before operation contained scarcely more than pus in microscopic quantity.

Dr. Albert A. Berg asked Dr. Brown whether he was able to determine the primary infection in this case; whether he considered it due to a blood infection or an ascending infection from the bladder? He stated that at the Mt. Sinai Hospital during the past summer they had seen a number of cases of septic infarction of the kidney after a local osteomyelitis of the finger or toe which had been successfully treated by nephrotomy and drainage, and he raised the query whether a nephrectomy was necessary unless there was distinct disorganization of the kidney.

Dr. Martin W. Ware asked Dr. Brown how he harmonized the fact of a large palpable tumor of the kidney and the subsequent statement that there were miliary abscesses alone found in the kidneys upon its removal.

Dr. Brown, in reply to Dr. Berg, said that in the case presented, there were multiple bean-sized foci, and the appearance of an acutely and extensively infected kidney was such that he considered a nephrectomy not only justifiable, but imperative. So far as the primary source of infection was concerned, there was a history, and still evidence of a recent boil on the right side of the abdomen, but there was no record of any bone or periosteal infection. He was inclined to believe that the case was one of blood infection, possibly from the abdominal sore.

Dr. L. Bolton Bangs said that no hard-and-fast rule could be laid down in regard to cases in which a nephrotomy or a nephrectomy should be done. He recalled cases of disorganization of the kidney in which the diseased organ had apparently recovered a fair degree of function after simple drainage, and he emphasized his belief that unless there was some hazard to the patient from the presence of acute sepsis, it was wiser to do a preliminary nephrotomy, a subsequent nephrectomy depending on the future course of the case.

Dr. Brown said that in dealing with a case of multiple miliary foci, involving the kidney, it was not easy to see upon what surgical grounds one should open the kidney at all. Merely to drain the surfaces of such an incised kidney would accomplish little or nothing unless, perhaps, in making the incision, capsular tension was relieved, and by reason of it, a more favorable circulation established in the kidney. A contraindication to incision and drainage was that the infection was then brought in contact with the areolar tissue about the kidney, whereas, by nephrectomy the organ could be moved without soiling the surrounding tissues.

Dr. Berg, in reply to the point raised by Dr. Brown in regard to the possible effect of incision and drainage in kidneys that were the seat of miliary abscesses, and the danger of infection connected therewith, said that such had not been their experience at Mt. Sinai Hospital in dealing with multiple foci of the liver. In about eight such cases that had come under their observation, in which there were clinical evidences of single or multiple foci of pus in the liver, multiple punctures of the liver, with or without free exposure, had been followed by improvement. Similar observations had been reported in England.

Post-operative Neurosis.—Dr. F. Tilden Brown also reported the case of a married woman, 49 years old, upon whom he had done a right nephrectomy two years ago. Towards the end of an excellent convalescence she claimed that she was subjected to a draught, which produced a distinct neuralgic pain in the head, and this idea had persisted and grown more pronounced since. These pains were not now limited to the region of the operation, and Dr. Brown said he had become convinced, both by his own observations and those of a neurologist who had repeatedly examined and recently treated the woman for nearly two months of late, that her pains were of a neurotic character and not the result of a nerve trauma. The operation in this case, the speaker said, was a nephrectomy for a chronic septic condition of the kidney, with occasional angulation of the ureter and intermittent pyonephrosis. There were also occasional attacks of hematuria and severe pain, and these latter were the symptoms that most impressed the patient. She made a thoroughly good recovery from the operation, and it was not until two weeks later that she began to complain of vague pains, which, as stated, she attributed to a draught.

Ureteral Calculus with Unusual Characteristics.—Dr. Follen Cabot reported the case of a man 32 years old who came to the Post-Graduate Hospital complaining of intense pain and inability to urinate, the symptoms having suddenly come on while he was engaged at his work as a house painter. There was agonizing pain extending all over the bladder area; there was no pain in the back, groin, testis, or scrotum. A catheter was introduced into the bladder, and about half an ounce of clear urine withdrawn. His temperature on admission was 100°; he vomited, and the skin became clammy and cold. Suspecting the pres-

ence of a stone in the ureter, Dr. Cabot introduced the cystoscope under ether. The bladder, as well as the left ureteral orifice, was normal in appearance, but just inside of the right ureteral orifice a small calculus was seen. Cystoscopic forceps was thereupon introduced, and the stone was grasped and removed. It unfortunately dropped into the bladder, and on account of the patient's condition no prolonged efforts were made to remove it. When he recovered from the effects of the anesthetic he was entirely free from pain, and he left the hospital on the second day. The stone was not recovered, although he was instructed to pass his urine through gauze and report in a week, which he failed to do.

Dr. L. Bolton Bangs said he had seen a few cases of ureteral calculi in the lower segment of the ureter, and in most of them the stone had passed spontaneously. In order to expedite this, Dr. Arthur Cabot, of Boston, in a recent paper on this subject, recommended the very common and simple procedure of massaging the ureter. The speaker said he was convinced that most of these calculi would pass with a little aid on the part of the surgeon.

Dr. Martin B. Ware said he had recently encountered two cases in which the symptoms indicated the presence of a renal or ureteral stone in the act of passing. In one instance the patient had submitted to an operation for quasi-appendicitis, which failed to give him any relief. An *x*-ray examination disclosed the real state of affairs and an operation was advised. He then consulted Dr. Ware, who cystoscoped him and found a calculus near the ureteral orifice, and within twenty-four hours this had escaped into the bladder. The speaker expressed the opinion that pain in itself did not justify exposure of the ureter, and that the operation should only be done in dealing with calculi of considerable size attended with systemic infection. In the case just reported the stone was as large as a cherry pit. In the second case, with a somewhat similar history, the stone was about the size of a barley corn and also escaped spontaneously into the bladder.

Dr. Follen Cabot said that while it was well known that these stones frequently escaped spontaneously into the bladder, still in cases in which the patient was suffering great pain he saw no reason why an attempt should not be made to relieve it. He saw no harm in the careful use of the cystoscopic forceps. There were cases in which the stone never got beyond the ureteral outlet, and to allow it to remain there was apt to produce permanent damage in the kidney.

Operation for Bilateral Undescended Testis.—Dr. Martin W. Ware reported the case of a boy, 14 years old, who had been operated on by him for double undescended testis. The case at the time had seemed a very promising one for operation; the testes were outside of the ring and of good size, and they gave rise to a good deal of pain in their abnormal position. The left side of the scrotum was very undeveloped. The Bevan operation was done, comprising a very free division of all the structures that made up the cord with the exception of the vas deferens. The immediate after-effects of the operation were excellent, but in the four months that had elapsed since, a recurrence on both sides had taken place. The operation, therefore, was not a success.

Dr. Oliver C. Smith of Hartford, Connecticut, exhibited a large "mulberry," prong-shaped calculus composed of calcium oxalate, weighing 4.55 grams, which had been extracted from the bladder of a man fifty-six years of age during an operation for carcinoma of the prostate by the perineal route. The operation was performed in February, 1906, by Dr. George N. Bell, and the patient was still living.

Dr. Smith also exhibited a clear *x*-ray picture of a renal calculus. The calculus, which had been removed at subsequent operation (June, 1905), was also exhibited. The features of the exhibit were, first, that it had a historical interest, as it was the first operation for nephrolithiasis following *x*-ray diagnosis, in Hartford County, and, so far as the author knew, in the State. Second, the size of the shadow in the picture and the stone were the same, demonstrating the importance of a quick exposure while the patient's breath was held. The skiagram was made by Dr. A. C. Heublein of Hartford.

Dr. Smith recited a case of a portion of a glass catheter in a female bladder. The patient was at the Litchfield County Hospital. She had been catheterized carefully by an excellent nurse, but when the catheter was withdrawn it was found that 2 cm. of the distal end had been left in the bladder. It could not be reached or felt by sound or forceps. Upon cystoscopic examination it was found and a mucous fold at the base of the bladder and removed without incident. The speaker emphasized the importance of examining a glass catheter, especially after boiling, before it is introduced into the bladder, to prevent similar accidents.

The Preparatory and After-Treatment of Genitourinary Operations.—Dr. L. Bolton Bangs said that his experience as a hospital surgeon, together with his observation in private practice, had forced him to the conviction that not enough time was usually given to preparation of the patient for operation. This did not apply to the many emergency cases which we were compelled to accept, and which, of course, were of necessity treated without preparation. Many cases came to the surgeon in a state of physical debility, either from intemperance, overwork, or starvation, or all combined, whose prospects of speedy recovery could be vastly improved by sufficient and careful preparation for the contemplated operation. Among surgeons in the large city hospitals it was a common experience to observe the almost magical effect of a few weeks or days in the hospital upon these patients of degraded tissue, and even after a short postoperative period we saw them go out with a richer quality of blood and with a cheerfulness of spirit which were in marked contrast to the bodily and mental conditions with which they entered. In genitourinary, as in all departments of surgery, there were many simple operations which might be performed without any special consideration of the patient's condition; but it should be remembered that the patient's excretion of urine was a paramount function, and that the vital function of reproduction affected certain activities of the brain, spinal cord, and heart. Hence, the relations between the different organs essential to these functions and between them and the general organism were so intimate and so important that every means should be taken to prevent any interference with these relations. Any local inflammation, no matter how mild, should first be subdued. These same principles should be applied when the ligation of a varicocele or excision of a hydrocele or castration was to be undertaken. Too often we performed these without any preparatory treatment, and with very little consideration of the patient's other conditions. Operations upon the urethra should always be preceded by careful preparatory treatment, particularly in the cases of stricture. In these cases, too, the postoperative treatment was most important. Dr. Bangs said that in his opinion the so-called "urethral splint," meaning a catheter through the whole length of the anterior urethra and fastened in place, was uncalled for after stricture operations. It was an irritant which not only provoked erections, but must of necessity interfere with the healing process. Too frequent instrumentation after an operation on the urethra was another form of irritant. In operations on the bladder and prostate, preparatory, as well as after-treatment, was most important. Nitrate of silver was one of the most useful of bladder disinfectants, but it must be in mild solution and used judiciously. Strong irrigating solutions, and especially nitrate of silver, were contraindicated in cases of suspected stone in the bladder. In such cases, abso-

lute repose in bed and the gentle use of weak antiseptics, like boric acid, would soon modify the symptoms so that a positive diagnosis might be made. Operations upon the kidneys were always of such vital importance to the patient that good judgment must be used in the application of these general principles. Exclusive of emergency cases, in which delay might be dangerous, especially in cases of anuria, preparatory treatment was very important.

Dr. George K. Swinburne said he was strongly in favor of letting the urethra alone after internal urethrotomy, but his experience applied only to that; he had never applied it after external urethrotomy. He fully agreed with Dr. Bangs as to the value of preliminary treatment in genitourinary operations, even in ambulatory cases, and decidedly so in operations on the prostate, and he could recall instances where the preparatory treatment of such patients undoubtedly proved a life-saving measure. He also spoke of the utility of sterilizing the urinary tract and preventing urethral chill.

Dr. A. A. Berg asked Dr. Bangs whether he had found that the administration of the formaldehyde compounds had any effect on the healings of the wounds. Personally, he had had no experience with wound necrosis after the use of these drugs.

Dr. Edward L. Keyes, Jr., said he habitually gave this drug after operations on the genitourinary tract, and he could only recall one instance where it was apparently responsible for a tanning of the wound surface. The case in question was one of suprapubic prostatectomy. He had never seen or heard of any postoperative complications arising from its administration before operation.

Dr. Martin W. Ware said he had had this possibility of a cauterizing action of the drug brought to his attention by some of his associates, but he failed to see how it could be held responsible in those cases where the bladder itself was infected. The speaker said he invariably gave it in connection with operations on the genitourinary tract, and in those cases where urethral instrumentation was necessary for the purpose of dilating a stricture or the use of a searcher, he always followed the procedure with a dose of quinine, with the hope of averting a urethral chill. He recalled, within the past two months, two cases of urethral chill and fever following an external urethrotomy and the passage of an instrument into the urethra, though both had been subjected to careful preparatory treatment. Both made a good recovery.

Dr. Victor C. Pedersen said that at the House of Relief, where a heterogeneous group of genitourinary patients who had abused themselves in all sorts of ways were constantly under treatment, he had seen no case of urethral chill during the past three years. The rule there was to exercise great care in the selection of patients into whose urethras instruments were introduced. Patients who gave a history of previous operation for an old urethral stricture were apt to be sent to the hospital, and were otherwise submitted to preparatory treatment before the introduction of an instrument, because even such a simple procedure as passing a sound might lead to serious results in these cases. Before or after instrumentation the patients were given a cardiac stimulant and arterial dilator, such as nitroglycerin in asthenic cases, or, in the sthenic type a cardiac sedative and arterial dilator such as aconite, and perhaps a small dose of morphine or codeine. Quinine was also given in all cases. This combination was suggested by Dr. Robert F. Weir to Dr. Pedersen, while House Surgeon at the New York Hospital. No urethral chills and no reflex anuria were seen there during his term of six months' duty. The doses used by Dr. Pedersen were: Nitroglycerin gr. 1-50, or fluid extract of aconite ♏iii, quinine sulphate gr. v-x, codeine gr. i, or morphine gr. 1-8.

Dr. Bangs, in closing, said he did not object to the use of the inlying catheter. On the contrary, he used it constantly and only objected to it after internal urethrotomy or after a combined internal and external urethrotomy, when the catheter was tied into the whole length of the urethra. The speaker said he used utrotropin habitually, both before and after operation, and had never seen cauterization of the wound surfaces. Occasionally one saw the wound surfaces coated with phosphatic material, but that was not due to urotropin.

Unilateral Pyelonephritis.—Dr. Martin W. Ware showed the specimen in this case. It was obtained post-mortem from a patient upon whom he had done a prostatectomy one month prior to the final operation on the kidney. The history of the case preceding prostatectomy was that the patient had had several attacks of acute vesical retention, and attempts to enter the bladder gave rise to free hemorrhage. He was finally cystoscoped, and a vesical calculus and an enlarged prostate were found. Prostatectomy was done in two stages. About a month later the patient complained of pain over the left kidney, with increased leucocytosis and an irregular, intermittent temperature. The left kidney was exposed and incised, and about a pint of pus evacuated about its upper pole. The kidney was incised and the wound was then closed, with drainage. Within 24 hours later the patient showed signs of diminished urine, which became an absolute anuria and ended fatally. At the post-mortem examination the kidney was found studded throughout with abscesses. The opposite kidney was found to be absolutely normal.

Pathological Society of Philadelphia and Philadelphia Academy of Surgery.

At a joint meeting, held February 13, a symposium was held on the "Parathyroid Glands." Dr. W. S. Halsted, Professor of Surgery in the Johns Hopkins Medical School, presented a communication entitled "The Parathyroid Glands in Their Surgical Aspects." He first detailed certain experimental observations that he had made, showing that the parathyroid glands could be removed from their normal situation behind the thyroid gland and be transplanted in some other situation, for example, behind the rectus abdominalis muscle, without the development of untoward symptoms; but when the transplanted glands were removed from their new site symptoms of tetany appeared. He pointed out that the parathyroids varied in number and location, although as a rule in man there were four of them, and they were usually situated within the capsule of the thyroid gland, although at times they are embedded in the structure of the gland. He referred to the case of a woman who developed tetany after inadvertent removal of the parathyroid glands during an operation for goiter and who had obtained a certain measure of relief from an anti-parathyroid serum. Dr. W. G. MacCallum, Associate Professor of Pathology in the Johns Hopkins Medical School, delivered an address entitled, "The Physiology and Pathology of the Parathyroids." He emphasized the structural and functional nonidentity of the thyroid and parathyroid glands. The parathyroids exhibited marked variability in number and in position in lower animals, although in man there were usually four and situated behind the thyroid gland. They were commonly in close relation with the inferior and superior thyroid arteries, from which they derived their nutritive supply. Their removal, and not that of the thyroid, gave rise to the symptoms of tetany, by permitting the accumulation of toxic substances in the blood. These symptoms could be induced when the muscles were isolated, but not when the nerves or spinal cord was divided, so that it might be concluded that the toxic effects were exerted on the central nervous system. Dr. MacCallum had found in experimental observations that there was a marked deficiency in the amount of calcium salts retained within the body in animals from which the parathyroids

had been removed, and that when symptoms of tetany developed under these conditions they could be checked instantaneously by the intravenous or subcutaneous injection of a soluble salt of calcium and less effectively by administration through the stomach. Accordingly, Dr. MacCallum has proposed the designation diabetes calcareus for the disorder. In the case of tetany cited by Dr. Halstead, administration of calcium lactate in doses of 4 grams seemed to afford relief from the symptoms, but, of course, hasty conclusions could not be reached from isolated experience. Dr. N. Ginsburg and Dr. J. J. Gilbride demonstrated dissections exhibiting parathyroids *in situ* and their relations to adjacent important structures. A discussion followed, which was participated in by Drs. E. A. Spitzka, H. A. Hare, John E. Deaver, A. O. J. Kelly, C. H. Frazier, J. Chalmers DaCosta and A. P. Brubaker.

Philadelphia Pediatric Society.

At a stated meeting held February 11 a symposium was presented on "Rheumatism in Children." Dr. Warfield T. Longcope read a paper, entitled "The Etiology of Rheumatism." He discussed the various microorganisms that have at different times been described as present in the articular lesions and the complicating endocarditis, but from a study of the literature and some observations of his own, he was unwilling to admit the specificity of any of these. He even went so far as to say that the streptococci and diplococci described as specific could not with certainty be differentiated morphologically or in culture from the large group of streptococci present in varied lesions under the most diverse conditions. He left the impression that the symptoms of acute rheumatism might be induced by any one of a large number of microorganisms. Dr. D. J. McCarthy presented a communication entitled, "The Relation of Rheumatism and Chorea." He defined chorea as an acute infectious disease concerning whose etiological factor we were as yet in ignorance. Inasmuch as the specific causative agent of rheumatism was likewise as yet unisolated, any direct relation between the two diseases could not be absolutely demonstrated. Observations by trustworthy clinicians, however, made it appear that rheumatism is or has been present in some 25 per cent. of all cases of chorea. Dr. Charles Hunter Dunn, of Boston, read by invitation a paper, entitled, "The Peculiarities of the Symptomatology of Rheumatism in Children." He dwelt upon the wide differences in the symptoms of the disease as observed in children and adults respectively. While in the latter articular symptoms are the most conspicuous, in the former lesions are most common. In children, also, the disease has a tendency to be more insidious in onset, more obscure in development, and more protracted in course. Dr. Alfred Stengel made remarks on "The Complications of Rheumatism in Childhood." He emphasized the fact that the cardiac disorder attending rheumatism in childhood is essentially a pancarditis, neither endocarditis, nor pericarditis, nor even merely a myocarditis, out, as a rule, a combination of all three. Dr. Jay F. Schamberg read a paper entitled "The Cutaneous Manifestations in Rheumatism in Children." He took the ground that rheumatism was not attended with cutaneous lesions peculiar to itself, but that such as appeared in connection with it were attributable to the toxic effects of the underlying cause of the disease, whatever this cause might be. Very similar lesions, he said, might be observed in connection with a variety of other infectious and toxic processes. Dr. J. P. Crozier-Griffith read a paper entitled, "The Treatment of Rheumatism in Children." He advocated especially the use of salicylates, particularly sodium salicylate, and the alkalies, sodium bicarbonate and potassium acetate.

New Instruments.

SIMPLE APPARATUS FOR ASPIRATION AND EVACUATION OF THE TYMPANIC CAVITY AFTER PARACENTESIS.

By PERCY FRIDENBERG, M.D.,
NEW YORK.
JUNIOR SURGEON NEW YORK EYE AND EAR INFIRMARY.

In a paper on the Treatment of Acute Otitis Media in Childhood* and in a number of subsequent publications†, I have called attention to the value of the procedure indicated in the title of this note. At various times, more especially since my last article on this subject, I have received letters asking where the suction-bulb which I described could be procured. As the method is gradually gaining ground, and is, as I am firmly convinced, a valuable aid in the removal of pus accumulations from the middle ear, a photograph of the little instrument and a few words as to its use may be of service to those who wish

to apply the method which I have recommended. As stated in my papers, no special apparatus is essential. Any glass bulb will answer which will plug the meatus without causing pain, has no sharp tip to inflict injury, is wide enough to be easily cleaned out, and will stand boiling. The ordinary, small-size ear-irrigating tip will do very well. The model I use is about the size and shape of an olive, measuring five-eighths of an inch by one inch, with a short shouldered neck, as shown in the accompanying illustration. The neck is stuffed with dry sterile absorbent cotton, and the glass bulb, after being boiled, is attached to a piece of stiff white rubber tubing about one and a half feet long, and of lead-pencil caliber.

The aspirating force may be supplied by a small syringe, or the lips may be applied directly to the

American Journal of Surgery, May, 1905.

†Aspiration of the Tympanic Cavity, etc. Medical Record, March 3, 1906. *Annals of Otology, Rhinology, and Laryngology*, September, 1906. *Journal of the American Medical Association*, January 4, 1907.

tube and actual suction made, as is the usual practice with the Siegle otoscope. While the syringe would appear more suitable from the standpoint of ideal asepsis and esthetics, there is no practical objection to suction, and this method has a number of real points in its favor. The sterile cotton in the neck of the bulb prevents aspiration of septic matter into the rubber tube. The degree of suction employed can be accurately gauged, as it is distinctly felt by the operator, and can be varied within wide limits. This is not the case with the syringe, which requires the use of both hands, and has to be of large size if it is to have sufficient aspirating power.

The ease with which this simple apparatus can be made ready for use, applied, and afterwards sterilized, its simplicity and portability are its great points of superiority over other complicated forms of aspirators on the model of the otoscope. Almost any druggist can supply the bulb, or procure it from one of the glassware-manufacturing houses at trifling expense. For removing matter from the middle ear for bacteriological examination it is perfect. Aside from the mechanical removal of septic matter, the factors of depletion, thinning of exudate, and increased flow of uncontaminated blood-serum to the middle ear, the active hyperemia induced without interfering with circulation or rather with venous outflow, and the aid to drainage are the valuable features of the method which has all the advantages of Bier's treatment without any of its objectionable and even dangerous features.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 29, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	451	204
Diphtheria	373	44
Measles	1554	39
Scarlet Fever	924	39
Smallpox	..	..
Varicella	180	..
Typhoid Fever	45	9
Whooping Cough	20	1
Cerebrospinal Meningitis	16	8
Malarial Fever	..	..
Totals	3563	344

Gifts for Charitable Objects.—During the year 1907 the Chicago *Tribune* estimates that the sum of $148,902,000 was given for philanthropic purposes. The list of donors is headed by John D. Rockefeller, Mrs. Russell Sage comes second, and Andrew Carnegie third. Mr. Carnegie's total gifts are said to amount to $170,000,000.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending February 28, 1908:

SOME OBSERVATIONS ON THE EFFECTS OF TOBACCO IN SURGICAL PRACTICE.*

BY L. BOLTON BANGS, M.D.,

NEW YORK.

LATE PROFESSOR OF GENITOURINARY SURGERY IN THE UNIVERSITY AND BELLEVUE MEDICAL SCHOOL; CONSULTING SURGEON TO BELLEVUE, CITY, ST. LUKE'S, ST. VINCENT'S, AND SENEY HOSPITALS.

THE purpose of this paper is not to make a dissertation upon Tobacco, but to give briefly some experiences which have had an influence upon the practice of the writer. It is also to suggest a topic, the discussion of which it is hoped will bring out the experience of others and perhaps correct any misapprehensions or unwarranted conclusions of the paper.

It is a common observation that when a man is sick he gives up tobacco spontaneously; that with convalescence the craving for it returns, and, apparently, the subject has experienced no ill result from the sudden withdrawal of the drug. This is especially true, I think, of strictly medical conditions; and from what I have observed in surgical states, I have been led to ask the question whether this apparent indifference of the medical patient to the withdrawal of the tobacco is not due to the supporting effect of the strychnine, alcoholics, and other cardiac stimulants usually administered. For, in surgical maladies, excepting in those cases in which the gravity of the general symptoms overshadows everything and demands supporting measures, there is sometimes a mental irritability and restlessness and, not infrequently, a vital depression not to be accounted for by the surgical state. What is the cause of these? I believe the withdrawal of tobacco. After awhile accommodation is established and other symptoms disappear; but, in consequence of the experiences which I am about to relate, I have, whenever the symptoms of the patient suggested it, not only winked at, but encouraged the surreptitious use of tobacco by my hospital-ward patients, and in private practice have advised the resumption of the habit at the earliest possible moment—even when the patient seemed too weak to draw on his cigar. I believe that the irritability and restlessness have been relieved and the convalescent period shortened by permitting the use of the tobacco to which they had been accustomed. Of course this applies only to the habitual users of tobacco, whose nervous system has become dependent upon it. Presumably a healthy man or one whose kidneys are in good condition, can consume a moderate amount of tobacco without any particular harm to himself, present or future, but it seems to me that notwithstanding the "pleasure and mental satisfaction" which the use of tobacco affords there is danger to that part of the sympathetic nervous system which presides over the functions of the heart and kidneys; especially when the habit has been begun in early life, *i.e.* before the end of the developmental period, which may be placed at twenty-one or twenty-two years of age. What this moderate or temperate quantity is, is an individual matter and must be determined by the man himself. But even when in health his consciousness of the proper amount is clear, and his will aroused to exercise the necessary self-restraint, I doubt if he ought to be left to his own judgment to determine what is best in a state of sickness. Some of the writers on the effects of tobacco have said that there is no particular danger in a sudden withdrawal of tobacco, that "abstinence symptoms" do not occur in the same sense as they do after sudden withdrawal of alcohol or morphine, but clinical observations have led me to an entirely different opinion.

Some years ago I performed internal urethrotomy upon a young man, aged twenty-six. His organs were all normal with the exception of an overacting heart, due to his inveterate overindulgence in tobacco, notably cigarette smoking. He had begun the habit in early boyhood and had gradually become absolutely dependent upon his daily tobacco. No untoward events occurred in regard to the operation itself. He had a skilled male attendant, he was surrounded by all the conveniences and luxuries of life, and on the sixth day after the operation, although I thought it advisable to keep him in bed, I informed him and his relatives that I would not be in again for two or three days, leaving word with his attendant to report to me in regard to his condition. On the second day thereafter I received an urgent note from his mother in which it was said that the young man was dying and that I must hurry to his rescue. Fortunately I was at home when the message was received and arrived at his bedside fifteen or twenty minutes later. I found the whole household gathered on the stairway and his mother and trained attendant hovering over the patient whose appearance was certainly alarming. He had slipped from the pillows down into the bed; his face was ashen; a clammy sweat covered his face and hands; he feebly responded to questions but made no voluntary movement or speech; his respirations were shallow and labored; and his pulse, feeble and distant, fluctuated widely in the few moments of hurried observation. He had the appearance of a man suffering from extreme shock. At first I could not account for the situation. The surgical conditions were all good. There had been no hemorrhage from the urethra and there had been no chill or rise of temperature. It was now about two o'clock in the afternoon and according to the nurse's account, although the night preceding had been a restless one, this morning he had eaten his breakfast as usual and nothing extraordinary had occurred. The nurse had left him to go to his own luncheon, but before he had finished he was sum-

*Read before the Practitioners' Society of New York, February 7, 1908.

moned by the mother and found the patient in the alarming condition which had increased to the one which I have tried to describe. At the head of the patient's bed stood a commode upon which was always a silver tray holding one or two packages of cigarettes, a small box of wax matches and always stumps of the innumerable cigarettes which he had smoked all through his illness. On noticing that the tray and its accompaniments were not there, suddenly a possible cause of his condition came to me, and I asked his mother if he had stopped his tobacco. She said "yes"; that in response to her urgent solicitations, which she had been making for several years, he had thought it a good opportunity to give up his habit and deciding that he could better stop short than taper off had sent the tobacco out of the room. His last cigarette had been smoked some time in the morning of the previous day, and although he had been restless and passed a wakeful night he had not complained and, as she said, prepared himself to fight it out. I immediately sent the attendant to a neighboring hotel for a package of cigarettes; meanwhile watching the patient, whose condition did not change very much excepting that some brandy and water, which he feebly swallowed, gave him slight support. On the return of the attendant in a few minutes, I placed a cigarette in the patient's mouth, lit it for him and told him to pull on it as strongly as he could. He took a few feeble whiffs, inhaling each time; and then, as his respiration became stronger, he inhaled the smoke vigorously. In a few seconds his usual color came back to his face, the sweat stopped, his heart beats became stronger and regular, finally settling down to about eighty, and before he had smoked one cigarette he pulled himself up in bed upon the pillows. This was all that I did for him. His return to life was rapid (to his mother miraculous), and my counsel, that acute illness, whether surgical or otherwise, was not the time for him to give up his tobacco, was readily accepted.

Two years after this experience I operated upon a gentleman aged thirty-three, for hemorrhoids. He was in a private room in a large general hospital and everything went on well till four or five days after the operation, when, on making my daily visit, I was met at the door by the house surgeon who said that the patient was not doing well and that I ought to see him at once. In reply to rapid questioning he stated that he did not know what the trouble was; that the patient had no elevation of temperature; that he could find nothing wrong in the surgical conditions, but that the man was in a state of extreme depression, approaching collapse, and he had found it necessary to stimulate him. The patient's condition was similar to that of the one previously described, but without the clammy sweat and with symptoms of lesser gravity. Finding no local cause for the vital depression and knowing that the patient used tobacco I asked him if he had stopped smoking and if he had not felt the need of tobacco. He replied that he had stopped because he thought it was against the rules to smoke in the hospital, and that he missed the tobacco seriously. Then turning to the house surgeon, I asked him if he had a cigarette. Of course he had one, which at my request he placed in the patient's mouth; then with practised dexterity igniting a match he lit the cigarette. The patient inhaled, at first feebly, then vigorously, and he, too, like the preceding one, in a few seconds drew himself up on the pillows, the color came back to his face, and the pulse beats mounted and remained at 75. Curious to note what effect this would have upon the house staff, without a word I turned and left the room. As I went out into the corridor, the house surgeon and his assistants close behind me, I heard the house surgeon make to his senior assistant, the unscientific, inelegant, but significant comment: "Well! I'll be damned!"

Now here are two cases which show the results of sudden withdrawal of tobacco and certainly contravene the common opinion, shared by scientific and lay observers, that a man can do this without detriment. As to the second case I confess that I was surprised at the profound effect. Unlike the first, who was a "cigarette fiend," this man was temperate in all his habits, rarely smoking over three or four cigars a day, with an occasional cigarette, but he was of delicate, sensitive constitution and more dependent upon the moderate amount of tobacco than he or I knew. Moreover the symptoms seemed to be the culmination of an abstinence of about a week, while in the first the shock came suddenly after an abstinence of only twenty-four hours. It is probable that the surgical conditions rendered these men more susceptible to depressing influences and less able to resist the loss of the daily stimulant. The majority of us are so accustomed to tobacco that its use or disuse seems simple and harmless, therefore trivial and not worthy of being taken into account when the important subject of a surgical operation is before us. Hence these cases were a lesson to me and opened my mind to the necessity of a broader consideration of the relation between the vital processes and tobacco, and the risk of withdrawal of the daily dose. They also strikingly illustrated the rapid stimulating effect of the tobacco by inhalation.

In further proof of the value of this consideration take the following case: A young man aged twenty-five was operated upon by one of my colleagues for appendicitis. Everything went well surgically, till, on the fourth or fifth day after the operation, his pulse became quick with a normal temperature and he manifested great irritability, restlessness, and insomnia. The neurotic symptoms continued with increasing severity for several days longer, when it was found necessary to give him morphine hypodermically in order to control his excitement. The vital depression was also so pronounced that it was proposed to give him alcoholics. These he positively and persistently refused; his reason being that he had witnessed the effect of alcoholic intemperance in his father and he vowed that he would rather die than take any alcoholic. At this stage I was asked to see him in consultation. He was restless, moving precipitately in the bed, twitching, apprehensive, and sleepless, excepting when under the influence of morphine. His pulse varied from 90 to 100 and he complained of great debility. As the patient was known to be of a neurotic family it had been taken for granted that his symptoms, in the absence of surgical cause, were due to his constitutional tendency. Probably I would have concurred in this view but for my previous experience and also from knowing that he was as intemperate in the use of cigarettes as his father was in alcohol. On inquiry it was found that the tobacco which had been suddenly withdrawn during the primary operative period had not been resumed. He was miserable without knowing why, and not recognizing any tobacco craving it had never occurred to the patient or to his attendant that his condition was due to the withdrawal of his daily dose of the weed. Cigarettes were ordered as one

would order strychnine or any other cardiac tonic, and convalescence was soon established. This young man was of neurotic parentage, of neurotic constitution, and although he could easily abstain from alcoholics he craved the stimulus of tobacco; this he subsequently combined with opium and for some years after was a wreck till he learned that he could not stop opium until he stopped tobacco, from both of which he has now abstained for several years. This leads me to quote a statement made to me by one of the good people who conduct missions among the degraded that they have made the observation that the majority of alcoholic inebriates cannot abstain from alcohol till they have first abstained from tobacco, and especially from cigarettes. I have no opinion as to the scientific value of this observation but offer it for your consideration.

In these cases it seemed to me that the heart had become accustomed to, and dependent upon, the tobacco; and that therefore, sudden withdrawal could not wisely be counseled. These observations strengthen the opinion stated in the early part of this paper, that the restlessness, depression of vital force, and melancholia of some of our ward patients may be due to the deprivation of their accustomed stimulant. Dr. Larrabee of Harvard University Medical School says that emotional strain, overexercise, insufficient or improper food, and indulgence in alcohol will predispose to some of the ill effects of tobacco, and states that a series of cases of angina appeared on a French man-of-war where the men, debilitated by scurvy and poor food, smoked to excess in a small, close apartment.* It is possible that some of these predisposing influences may, and they probably do exist in many of our hospital patients, but nevertheless, the relation of tobacco to the individual ought to be considered more than we are in the habit of doing.

PRELIMINARY REPORT OF A CASE OF CEREBROSPINAL MENINGITIS OF STREPTOCOCCUS ORIGIN APPARENTLY CURED BY SUBDURAL INJECTION OF ANTI-STREPTOCOCCUS SERUM.†

By GEORGE L. PEABODY, M.D.,

NEW YORK.

The patient is a man, 37 years of age, who was admitted to the New York Hospital on January 2 of this year. He gave the following history: His father, mother and one brother are all living and healthy. In his mother's family there have been two deaths from pulmonary tuberculosis; so far as he knows there is no other chronic or organic disease in his family. He does not think that he has had any of the acute infections of childhood. He has had a right inguinal hernia since the age of 13 years. Eight weeks before coming to the hospital he was struck by a trolley car and sustained bruises of the knees, right ear and face, and a slight scalp-wound, from all of which he made a rapid and complete recovery. He indulges freely in alcohol at times, and uses tea and coffee moderately. He denies venereal disease; he has lost most of his hair, however, and one epitrochlear gland is enlarged and palpable.

Present Illness.—He was feeling perfectly well until fourteen days before admission to hospital. On that day he was exposed to cold and wet, and soon thereafter on arriving at his home he had two severe chills. Almost immediately following the chills he felt quite feverish and complained of headache. This headache was severe and affected especially the top of his head and the temporal regions. Headache of this character has been present in greater or less degree of severity from that time until his entrance into the hospital. It is often most severe toward evening and during the night, though this is not invariably the case. When pains in the head are less marked his appetite is very fair, and he is able to take food and enjoy it, but if he attempts to take food while he has severe headache this is almost always followed by vomiting, which is not projectile in type. He is very nervous, and has slept but little during the past ten days. Three days ago he first noticed stiffness of the neck and pain in the muscles when he turned his head from side to side or bent it forward or backward. This stiffness of the neck has been steadily increasing in severity. Coincidently with the occurrence of the neck symptom he noticed pains and aches in the lumbar region. For the past seven days he has been growing very weak, and now feels markedly prostrated. There has been no cough and no epistaxis. His bowels have been constipated for the past few days. Except from weakness he has had no vertigo, and there has been no tinnitus, and no discharge from the ears. He has had aching pains about the eyes, but no disturbances of vision. His chief complaints on admission are constant headache, usually most severe at night, insomnia, fever, and prostration.

On admission he seemed acutely ill. His pupils were of moderate size, equal, and reacted to light and accommodation. His eye grounds were normal. His right external ear showed a short, recent scar on the lobe; but his ear drums were normal. His neck was stiff and painful on motion of his head. There was no tenderness over his frontal sinuses, or over his antra Highmori. His radial pulses were regular, equal, of good size and force, not rapid, of moderate tension. Arterial walls seemed thickened.

His heart was normal in all respects, as were also his lungs. Examination of his abdomen revealed nothing noteworthy. His knee-jerks were exaggerated, there was a very slight ankle clonus on both sides. Plantar reflexes were normal. Kernig's sign was present on both sides.

He was admitted at 6 P. M. on January 2. At that time his temperature was 100.6°, his respiration 26 and his pulse 112. On account of the severity of his headache an ice-bag was applied to his head, and later, a powder consisting of a small dose each of phenacetine, acetanilide and caffeine, was given to him.

At midnight he was still awake and suffering severely from pains in his head. Four ice-bags were applied to his head, so as completely to cover the vertex, and he received seven minims of deodorized tincture of opium.

During the night his pain was not relieved and he slept but little. The next day he had a chill which lasted twenty minutes, after which his temperature rose to 103.6°. His blood at this time contained 11,200 leucocytes of which 70 per cent. were polymorphonuclears. It contained no malarial organisms. Two days later the leucocytes had increased to 14,400 with 78 per cent. polymorphonuclears.

*See his article in the Reference Handbook of the Medical Sciences. New York: William Wood & Co.

†Read before the Practitioners' Society of New York, February 7, 1908

His fever from the start showed the wide excursions suggestive of sepsis, varying between 99° and nearly 104°; and this continued for thirteen days, or until after the first subdural injection of antistreptococcus serum into the spinal canal. The severity of the headache, its nocturnal exacerbations and the insomnia suggested the possibility of cerebral syphilis, but this hypothesis was soon discarded. Deodorized tincture of opium and morphine were the only agents that gave relief at night, and, even in full dose, these often failed to give sleep. Occasionally he was delirious at night, and his condition necessitated restraint to prevent his leaving his bed. Once in a while he vomited.

Two days after his admission blood was taken for culture but nothing grew in it in forty-eight hours. One subsequent attempt at blood-culture produced a similar negative result. No petechial or other hemorrhages occurred either in skin or elsewhere. His eyegrounds remained persistently normal. The day after his admission lumbar puncture was resorted to and six drachms of a slightly turbid fluid was withdrawn under distinctly increased pressure. It rose to a height of seventeen centimeters in a manometer, which, according to our observation, indicates nearly twice the normal pressure. It contained many leucocytes, some in a condition of degeneration. Of these leucocytes 72 per cent. were polymorphonuclears and 28 per cent. were lymphocytes; but cultures made from it, while revealing the presence of a Gram positive coccus, occurring in pairs and chains, composed of 8-10 individuals, left us in some doubt as to the exact identity of the organism. On January 10 a second lumbar puncture was done and sixteen drachms of slightly turbid fluid withdrawn which was found to be under 22½ cm. of pressure, or considerably more than twice the normal pressure. This had a specific gravity of 1.007, was of alkaline reaction, contained a faint trace of albumin and reduced Fehling's solution, on boiling. It contained many leucocytes, some degenerated. Sixty-one per cent. of them were polymorphonuclears and thirty-nine per cent. were lymphocytes. After forty-eight hours flasks inoculated with this serum showed a pure culture of a rather small streptococcus, many of them in long chains.

This settled the diagnosis as cryptogenetic sepsis, with localization of infection in cerebrospinal meninges, or subarachnoid space.

Although my previous experiences with antistreptococcus serum had been unsatisfactory (with the exception of a single case of scarlatina), on the 12th and 13th of January I gave him *subcutaneously* 10 c.c. of the serum. This was followed by no improvement in pain, fever, or general condition.

On the 14th I began *subdural* injections of the serum into the lumbar region of the spinal canal, and this was continued daily for four days. On each occasion a varying quantity of cerebrospinal fluid was withdrawn, and immediately replaced by ten cubic centimeters of anti-streptococcus serum. Then a day was allowed to pass before the fifth injection, and then after the lapse of another day a sixth similar injection was made. Thus he received in all six injections of 10 c.c. each of the anti-streptococcus serum into the spinal canal in a period of eight days.

After the second subdural injection, the spinal fluid proved sterile, and it was always found sterile thereafter; and on the day after the first of these injections the temperature fell for the first time below 99°; and from that time it fluctuated between 97.7° and 100° for six days. It then rose on two successive days to 101.4° and 102° respectively. It then fell to the normal and has now remained normal for twenty-six days.

The other symptoms steadily abated, the headaches being one of the earliest of them to yield to the treatment. Stiffness of the neck soon disappeared; but Kernig's sign could be observed until the 24th of January, since which time it has not been present.

After the subsidence of the headache he complained for several days of pains and cramps in his legs, and he required more or less opium at night occasionally to induce sleep; and at times he seemed somewhat dazed.

By January 25 practically all of his symptoms had disappeared and he was entirely rational. By the 29th he slept well without drugs; he was allowed to sit up and soon thereafter to walk about, and then to go out of doors daily. At the present writing (February 17) he looks and feels perfectly well and insists upon leaving the hospital to return to his home in Nova Scotia. He has remained in the hospital for the past two weeks only at my urgent solicitation; in the past seventeen days he has gained thirteen and one-half pounds.

It is worth noting that the attacks upon the spinal canal always caused pain, and that he thought the injection of the serum was followed by pain in the back and lower extremities and occasionally by aggravation of the headache; but I was led to insist upon its continuance because of the abatement of the fever and because of the sterilization of the spinal fluid which so soon resulted. Local anesthesia by ethyl chloride was the only attempt to diminish the pain of the procedure, and this was successful, of course, only in anesthetizing the skin.

Streptococcus cerebrospinal meningitis is rare, so rare, perhaps, that this experience may be of little general interest, but it seemed worth while to put it on record as being valuable as far as it goes.

SEPTAL HEMATOMA AND ABSCESS.*

By JAMES E. NEWCOMB, M.D.,

NEW YORK.

CONSULTING LARYNGOLOGIST, ROOSEVELT HOSPITAL; FELLOW AMERICAN LARYNGOLOGICAL ASSOCIATION.

Under this designation some observations are herewith offered on certain conditions which follow injuries of the nose and which occasionally appear without apparent cause and are, in the common phrase, idiopathic. I need hardly remind you that the use of this term, dating back to the old ideas on humoral pathology, is fast departing from scientific medicine. We may still use it in contrasting certain primary with certain secondary lesions, but it should always be with the understanding that idiopathic disease is merely disease without apparent cause.

Three clinical conditions within the scope of this brief paper have been described: 1st, hematoma; 2nd, abscess dating back to the classical description of Cloquet in 1830, and 3rd, serous perichondritis which is sometimes cystic. The term "perichrondritis" is objectionable, for, as we shall see, the perichondrium is not alone involved. All the septal layers participate in the process and sometimes the adjoining bone.

We shall better understand the subject if we devote a few words to a description of the mode of

*Read at the meeting of the Section on Laryngology, New York Academy of Medicine, Wednesday evening, January 22, 1908.

formation of the septum. Its cartilaginous portion is made up mainly of the quadrangular cartilage. In addition we have the columnar cartilage and the middle projections of the upper and lower lateral cartilages. The unossified strip of cartilage lying between the vomer and the perpendicular plate of the ethmoid is really a process of the quadrangularis, though receiving a separate name, the sphenoethmoid. A portion of the posterior segment of the quadrangularis sometimes assists in the support of the nasal bones.

Nasal development begins in the second month of intrauterine life. A slight groove appears at either side of the frontal protuberance. On each side of this groove two projections arise, the nasal processes. The outer pair form the external nasal walls while the inner pair unite to form the septum. These processes slightly diverging, grow downward and finally reach the floor of the nose, which is now at the tenth week formed by the union of the two superior portions of the mandibular arch. It will thus be seen that the septum is formed by the union of double structures. By the end of the second month ossification has begun on both sides of the primary septum. (Freeman.) This duality of the septum bears directly on the conditions we are considering this evening and accounts for the fact that the swelling due to hematoma or the inflammatory swelling due to abscess may appear in both nares and require treatment on both sides.

The most frequent cause of either variety of lesion is trauma, a blow or fall on the nose. A front blow seems more likely to set up inflammation leading to abscess than does a side blow, probably because such a front blow is more likely to separate the two united septal plates, thus permitting the accumulation of blood which offers a favorable culture medium for the growth of invading microorganisms. In many instances it is difficult to establish the relationship between a trauma and the abscess, for slight contusions easily forgotten may lead to hematoma and later to abscess. The latter may occur in connection with or as a sequel to typhoid fever, influenza, sinus disease, larvæ in the nose, tuberculosis, syphilis, dental cysts and caries, anthrax, glanders, measles, variola, and typhus fever. It has been noted after vestibulitis, furuncles, and acute and chronic coryza. In children it is more frequent during the first dentition and is doubtless more common in those of the scrofulous and rachitic diatheses. It has followed too forcible tamponing of the nose (case of Chavanne). Lederman has reported one case occurring after the removal of a bony spur with the saw. Erysipelas often finds its point of entrance on this septal site. It may lead to local abscess. Dantziger states that in women, the effects of a trauma are more apt to cause abscess if such trauma is inflicted during the menstrual period. Hecht declares that acute cases of perichondritis always follow influenza or aural trouble. Slow cases imply an infection of the nose on the area of least resistance. This author believes that hematoma without apparent cause is a characteristic feature of influenza, relating the histories of two cases tending to support this view. The first case was that of a boy of eight years who took influenza from his mother. He presented the usual intranasal swelling which proved to be a hematoma. The second case was that of a woman who developed an influenza during her menstrual period in which the characteristic swelling appeared as a hematoma but subsided without suppurating. This hemorrhagic tendency of influenza is manifest in the brain, ears, accessory sinuses, and in fact on the mucous surfaces generally.

An unusual clinical history is that given by Herek who relates that he was consulted by a woman of middle life who had had, eight days before, a very long bicycle ride in the hot sun and whose face still bore evidences of such exposure. On the day after the latter she had begun to have burning and discomfort in the nose, and when seen by the reporter presented the usual symptoms of abscess. Incision gave vent to serous pus, and examination revealed partial destruction of the cartilage. Herek referred the lesion to the exposure of the sun, but it seems more probable that it was due to the continuous impact for a long journey on a dusty road of dust-laden air containing infecting microorganisms.

The features of the cases referable to dental abnormalities are illustrated by a case of Killian's. A young man had pain in his left upper incisor tooth, and two days later, nasal obstruction, frontal pain, and high fever. On the seventh day there was a spontaneous discharge of pus from the left naris. The entire mucosa was swollen on both sides and elevated from the cartilage. The evidences of sepsis with the escape of pus from the naris continued. Free incision revealed the fact that nearly the entire septum had disintegrated. The bony septum was not involved. Healing resulted in fourteen days. The tooth referred to appeared sound externally. The patient went along without incident for six months when pain reappeared in the same tooth. It was extracted, but pus flowed from the socket and a probe could be passed two and one-half centimeters to the floor of the nose and the septal cartilage. A cyst was found at the tooth root. Its wall was removed and the cavity scraped. The cyst had evidently broken through under the septal mucosa in the initial attack. There was eventually a slight falling in of the nose. Killian states that he knows of two other similar cases. In one of Roe's cases, the abscess followed the filling of a tooth with amalgam.

Septal hematomata and abscess are among the unusual occurrences in rhinological practice. It is perhaps hardly true to say that they are rare. Lambert Lack met with twelve instances in a series of 17,000 cases seen in routine clinical work. He estimates that they occur once in about 1,500 to 2,000 cases. Up to the date of publication of his classic treatise, Morell Mackenzie had seen but one case of hematoma and one of abscess. On the other hand, Ruault of Paris declares that he saw between 70 and 80 cases of abscess in the course of eight years at one single institution. Wroblewski reports 14 cases, the largest number I have found definitely enumerated by any single authority. Three hematomas and 14 abscesses have come under my own observation in about 14 years. It would be of interest to learn from the experience of those present as to the matter of frequency.

When we consider the frequency of trauma in this region, it is rather difficult to say why these particular lesions are not more common. Some have supposed that the bacteriological effect of the nasal mucus inhibits the activity of the pus cocci in this region. The natural drainage is of course free. We know that while vascular parts bleed freely, this very vascularity enables them to recover themselves, so to speak, the more freely. As above noted, the severity of the trauma seems to be of less import than its direction in the matter of abscess formation.

A consideration of those cases without apparent cause leads us to bear in mind the histology of the mucosa in this region. It is extremely thin, not more than 1.5 mm. in thickness. One authority (Bargy) goes so far as to say that at the central

spot of the anterior inferior septum, there is practically no cartilage whatever and that the two layers of mucosa are in contact. He refers to this condition as a "physiological" perforation. Regardless of the thinness, however, the mucosa here presents four distinct layers: (1) a layer of cylindrical epithelium, becoming more pavement in character anteriorly and inferiorly; (2) the usual basement membrane; (3) a mucous chorion of two strata; 1st, a superficial stratum with mucous acinous glands and 2nd, a deep stratum carrying the nutrient vessels; (4) a connective tissue layer binding the mucosa to the cartilage. The attachment to the cartilage at the anterior inferior area is very close.

Now it is just over this area that the dust-laden air makes its initial impact on the intranasal structures and consequently the area is a favorite site for erosions. It is the site from which the blood most frequently comes in epistaxis. It is the favorite region of dalliance of the fingernail of the nose-picker. It receives the full force of any trauma. No wonder, therefore, that it offers an unusually favorable opportunity for the entrance of infecting organisms. The sequence of events is simple and easily explained. The germs generally found are the *Staphylococcus pyogenes albus* or the various streptococci. The symptoms are those which might naturally be expected and need not be enumerated before this audience. The characteristic feature is the bilateral swelling. Pus thus confined may give surprisingly little trouble except nasal obstruction. Not uncommonly the whole tip of the nose is red and tender. At times the inflammation may run out on to the cheeks or up to the eyelids and temples.

In hematoma, the blood effuses under the perichondrium. This may subside or become infected and go on to breaking down. The fluid takes on a brownish-yellow appearance looking like neither pus nor blood. This is the condition designated by some writers as "cold abscess." If the case is non-traumatic and runs an acute course, it has been called "acute perichondritis," but as we have noted the perichondrium is not alone involved and hence the term is objectionable. Jurasz, Massei and others have described a form in which the fluid becomes distinctly serous and call it "serous cyst." Obstructive symptoms may appear in the eyes as epiphora and conjunctivitis. Of course the fluid may be purulent from the beginning. Casselberry aptly observes that "some sort of abscess is the culminating stage of all these conditions."

Why is the abscess bilateral, an incision on one side not always evacuating the other side? It must be remembered that the cartilage here is really a fusion of two plates which have become separated by the trauma and the inflammation to which it gives rise. The effusion of blood raises the perichondrium on each side. Moreover the fused plates may become fractured thus offering communication from one side to the other. The tissues may degenerate and the effused pus often contains bits of grumous material. Probably in most instances the cartilage undergoes carious changes but generally the mucoperichondrium is sufficiently preserved to make good this loss. Large sloughing is unusual as is also invasion of bone, though Killian reports one case, that of a young man of 21 years, with the usual swelling of the nose and also of the hard palate. Incision of the former gave exit to clean, creamy pus; of the latter, to a few drops of foul, watery fluid. At this time no perforation could be detected. One was discovered, however, eight days later, and after another similar period the patient spat out two bony sequestra, leaving a small communication between the mouth and right naris. No trace of constitutional syphilis was discoverable in the patient.

An interesting question in these cases is that of a later deformity. We know that nearly or quite all the cartilaginous septum may go without distorting the contour of the nose. Some have contended that this follows here only after extensive cartilaginous destruction; others that it may occur after slight destruction provided that the force and direction of the trauma are sufficient to dislocate the cartilage from the vomer. Roe declares that the destruction of the small cartilaginous plates on the nasal dorsum is of greater significance with reference to deformity than is that of the quadrangularis. These small plates serve to connect the shield cartilage of the dorsum and the nasal bones. The writer believes this view to be a correct one. The deformity is not of the usual saddle-nose variety but is lower down on the dorsum. To use Roe's words, "it gives the central portion of the nose a depressed appearance as if the person had been struck on the top of the nose with a small round body like a poker." In simple abscess there is merely destruction of a part or the whole of the cartilage while the soft tissues remain intact, whereas in syphilis the soft parts are frequently destroyed with the cartilage, leaving a large perforation in the septum and a corresponding depression of the central portion of the nose.

Lambert Lack states that post-abscess deformity may be due directly to the injury, appearing at once, or it may not come on till some years later. In these slow cases it may be referable to the gradual contraction of the connective tissue following the injury or it may be that the injury has stopped the further natural growth of the parts so that the nose develops unevenly.

Treatment is simple in case of hematoma. The usual cold applications may be made over the nose and its interior kept clean. If the contents seem fluid they may be aspirated and firm bilateral pressure made by some form of tube or tampon, preferably the former. Serous cysts should be incised and their cavities scraped. The incision should be a generous one.

In case of abscess the sooner and the more freely the incision is made, the less liability to destruction of cartilage and deformity. At times it is extremely difficult to keep up proper drainage. Strips of gauze or tubes inserted through the incision will not stay in place. Ernest Waggett has suggested the thrusting through the incision of a knotted loop of horsehair. A seton may also be employed. The abscess cavity should be thoroughly flushed with peroxide solution followed by some alkaline antiseptic, but it should never be packed. In some instances of pus reaccumulation I have opened the cavity with the galvanocautery. In case of unilateral abscess it is of value to tampon the mucosa against that of the opposite side, rubber protective being placed in contact with the mucosa. The cavity is thus obliterated by pressure.

Lennox Browne notes that in the event of extension of the suppuration the point of evacuation should be in the buccal vestibule inside the upper lip above the central incisors, this site constituting that of least resistance. Such a procedure has never been called for in the writer's experience.

This comprises 3 hematomas and 14 abscesses. Of the entire number, 11 were due to trauma, the others to unknown causes. One of the hematomas came on without known cause and the other two were traumatic. There was no history of influenza

in the spontaneous case. One hematoma subsided and the other two went on to suppuration. When hematomas are incised they quickly become infected unless the clots are thoroughly turned out and the cavity cleansed and sealed. The ages of the patients varied from 2 to 41 years. The ages of the patients with hematomas were respectively 2, 8 and 18 years, the first being the case without known cause. In the abscess cases the time elapsing between trauma and appearance of symptoms varied from 5 to 21 days. None of these cases presented any special features. These statistics are defective with regard to deformities. They were all hospital cases and as long as they remained under observation no deformity was apparent. Their later history is unknown.

RENAL AND URETERAL CALCULI COMPLICATING OR SIMULATING APPENDICITIS.*

By JOHN F. ERDMANN, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF SURGERY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

PAIN in the lower right quadrant of the abdomen does not usually signify appendicitis, but may be associated with hernia, renal calculus, whether renal or ureteral in location; ovarian invasion, appendicitis, etc. It therefore behooves us, when seeing a patient complaining of pain in this region, to carefully eliminate each of these possibilities, and in so doing "McBurney's point" when present should carry weight only of the greatest elasticity rather than of definite and positive certainty.

During the past few years I have been fortunate in having a series of patients with renal and ureteral calculi, each either complicating or simulating appendicitis. Several of these were so confusing in their symptom complex as to require lengthy observation and the uses of all the modern appliances and physiological, etc., analyses to arrive at a satisfactory diagnosis. In fact, in one of these cases the symptom complex was such that a chronic appendix was diagnosticated by several prominent surgeons and medical men, myself included, and one medical diagnosis only was made of calculus. Each side was correct, as was proven by two subsequent operations (see Case I).

Naturally our difficulty in diagnosis arises only in the slow cases of appendicitis and in the types designated as interval, in which no typical acute attack has ever been evidenced. On the contrary, only those cases of stone presenting slight evidence of impaction, or slight to no marked urinary, etc., symptoms are mistaken for appendicitis. It may be rather a coincidence that in my series of patients all had some definite macroscopical appendicular evidence and evidenced some abdominal history in addition to that of pain and tenderness in the McBurney area.

Diagnosis.—Differential diagnosis in those cases characterized as interval, recurring, or chronic appendicitis is only to be definitely reached by a close urinary examination followed by radiography, and occasionally by ureteral examination with the waxed catheter or bougie. While in the acute variety, when history points to the possibility of calculus, the association possibility must be fully weighed and all factors closely analyzed for a dual disease.

*Read before the Yonkers Practitioners' Club, December 18, 1907, and the Physicians' Club, New York, January 29, 1908.

Pain.—In the great proportion of stone cases, no matter what position the calculus occupies, from the kidney to the ureteral insertion into the bladder, either one or combinations of the following painful areas are present: Testicular, penile, and inner surface of the thigh (G. Crural), while an additional, and this the confusing factor, pain is frequently elicited by pressure in the so-called McBurney area. This latter symptom may be due either to a reflected pain from stone in the hilum (see Case I), or, as in several of the other cases, when the stone is impacted in the pelvic portion of the ureter near the spine of the ischium. This pain is to be differentiated from that of an appendicular one by the fact that rigidity of the abdominal muscles is not usually present. That relaxation of pressure, Blumberg's sign (i.e. suddenly removing the palpating hand) is not followed by the pain usually seen in acute appendicitis. That pressure pain is not usually increased in a line toward the umbilicus, as in appendicitis, but may be so in a line toward the inguinal canal following the course of the ureter. That coughing and deep respiratory pain as seen in appendicitis is unusual in calculus cases.

Recently I removed a gangrenous appendix from a young man twenty-one years old, whose onset symptoms were characteristic of an appendicitis, but whose subsequent ones were typical of stone. He states that he vomited at the onset, but subsequently his pain, which had been umbilical, became testicular, with retraction of the testicle and scrotum, that he had sharp pain in his glans penis, and also complained of some urinary symptoms. Urine analysis was negative, and upon anesthetizing him on the third day of the disease, twelve hours after he was first seen by me, a mass was made out in the line of his right spermatic cord abutting upon Poupart's ligament.

The onset in calculus colic is not usually accompanied by the generalized abdominal, epigastric, nor umbilical pain that we see so often in appendicitis. Vomiting may be present in both, although present in greater frequency in appendicitis, and as a symptom is only a factor when taken with others as corroborative in a chain of symptoms that become positive guide posts to either disease.

Elevation of temperature, usually present (one might say always, if taken by the rectum) in all acute and subacute appendicular invasions, is not present in calculi cases except there be an infective process in the kidney, etc.

Pulse.—This factor can only be relied upon when taken in series with vomiting, temperature, etc. While it is true that marked acceleration usually accompanies acute cases, it is also true that the difficulties in diagnosis arise in the recurring, interval, etc., types, and in these the pulse is relatively of no assistance.

The previous history must be carefully weighed in arriving at a conclusion of either of these diseases. When one obtains a history of previous gastro-enteric difficulties, such as constipation, flatulence, sense of weight in the abdomen after eating, difficulties in digesting certain articles of food to such a degree as to cause the patient to shun them, a sense of weight in the right lower quadrant requiring the occasional placing of the hand to the side to adjust one's self as it is often expressed, then distinct and positive appendicular disease must be considered.

Pain in the back, loin, groin, inner surface of the thigh, urethra, testes and penis in the male, and vulva and urethra in the female, with occasional frequency of urination definitely points to a possible renal calculus.

Finally for the exclusion of appendicitis or for the dual diagnosis of appendicitis and stone, the urine and its channels must be carefully examined. The microscopical evidences in urine analyses that weigh in the diagnosis of possible stone are the presence of blood, crystals of oxalates and urates in excess, and epithelial elements from the hilum and ureters.

Blood may be present in the urine in cases of appendicitis due either to a toxemic nephritis (acute), or to some associated condition, as acute nontoxic and chronic nephritis, or floating kidney, etc. Blood without other renal elements, and in the absence of other pathological lesions of the bladder, urethra, etc., is the best diagnostic factor of stone we have, barring the evidences of a definite shadow in a radiograph or the scratch marks, made by contact with the stone, found upon a waxed ureteral catheter or probe that has been introduced into the ureter.

Cystoscopy.—In stone in the ureter, the cystoscope usually shows a definite and diagnostic change in the mouth of the ureter upon the affected side, characterized by redness and eversion or thickening. Should the stone be in the ureteral orifice it may be seen as a dark object in or protruding from the ureteral opening.

Radiography.—No better diagnostic means is at our disposal than the use of the *x*-ray, as in practically all cases the shadow of the calculus is seen if the patient has been submitted to an expert radiographer. Failures in radiography are due to the subject being old and feeble and suffering from calcareous degeneration. Failure is also likely in too fat subjects and some few cases of uric acid or urate stones, although according to Dr. Caldwell these latter varieties, *i. e.* the uric and urate stones, are usually depicted on the plates in the lean or moderately well developed patients. In the cases where the symptoms point almost definitely to the presence of calculus, and no shadow is seen upon the plate, it is necessary to examine the urinary channels. Cystoscopy for a picture of the ureteral orifice and the use of the waxed catheter or bougie into the ureters.

Stones simulating appendicitis are more likely to be found in that portion of the ureter between the pelvic brim and a point just below the ischial spine, although in Case 1 the spot pain was distinctly McBurney after the appendectomy, and the second *x*-ray showed the stone in the terminal portion of the hilum lodging in the extreme proximal portion of the ureter.

Operation.—The method of approach in calculi considered in this paper will depend upon the position of the stone.

When, as most usual, the stone is in the portion of the ureter stated above, it is a decidedly simple matter to approach it either by the transperitoneal route through a Deaver or Kammerer incision, removing the appendix, palpating the course of the ureter and finding the location of the stone. Then by a narrow extraperitoneal dissection from the outer margin of the incision one rapidly reaches the site of the stone, the ureter and stone being held transperitoneally and pushing upwards. Then through the retroperitoneal dissection the ureter is incised over the stone, the stone expelled and the ureteral wound sutured or not, a small drain put down to the trauma in the ureter. The peritoneum is then sutured and the muscles and skin sutured to the emergence of the drain. There is no necessity of suturing the wound in the ureter, as on several occasions I have left it without suture. In two of such cases absolutely no typical leakage occurred.

I prefer the transperitoneal localizing method as it is rapid; one can hook the fingers under the ureter and push it up without contusing it as is done with the usual instruments required in the retroperitoneal method. In the retroperitoneal method one must make a very long incision and dissect up a large amount of the pelvic and abdominal anatomy before arriving at the site of the stone. When the stone is situated high in the abdomen or is in the hilum of the kidney, the incision is either the oblique lumbar or the incision of Israel. One need not hesitate in either of these operations, provided the renal association is not infective, to explore the appendix through a nick in the peritoneum, and remove it, as it is readily found even in the usual incision of Edebohl for nephrorrhaphy.

I herewith report but three cases, not desiring to burden you by repetition.

Case I.—Mr. W., 42, was seen by me in December, 1903, with Dr. Youngling. At that time he stated that previous to August, 1902, he was well, except say ten years before had had intestinal colics, of which three were severe, and that they would lay him up for a day or so. That in eating late suppers, excess in food and eating cheese would also induce severe intestinal colic.

In August, 1902, during the night he had a sharp pain in the groin. In October, November and December of the same year he had pain in the right iliac fossa directly over the usual appendicular site, covering an area the size of the palm of an ordinary hand. The pains very severe would last from two to three hours, and then subside in the course of a day or two. These were accompanied with nausea and vomiting. He was and is unable to eat foods such as tomatoes, peas, corn, or potatoes. The bowels are regular. Urine had a trace of albumin a year ago; now Dr. Youngling says the urine is negative. Never had any pus or crystalline deposits. Loss in weight dates from January, 1903, at which time he weighed net 204 1-4 pounds. To-day, December 18, 1903, he weighs 160 pounds. He has been dieting. The patient has never been jaundiced. No temperature has even been recorded. An *x*-ray has been taken and was found negative.

He has had various diagnoses made, one of kidney calculus by Dr. Potter, who found a few corpuscles of blood in the urine; others of abdonimal lesion of some unknown variety. Mine was appendicitis with possible calculus.

Examination.—Painful spot in the left side of the body, and pressure pain in the region of his appendix.

Reexamination, January 26, 1904.—Loss of flesh of six pounds in three and a half weeks. Has had pain in the region of both spermatic cords and in the bladder.

February 2.—Submitted to exploration. Deaver incision three and a half inches long was made. Exploration of pelvic and iliac fossæ. Contents on left side normal. In the right iliac fossa numerous well developed bands of old organized adhesions were found. The appendix was buried in dense adhesions and was sharply flexed downwards, inwards, and forwards. The proximal portion was a dense fibrous cord one-eighth to one-sixteenth of an inch in width, while the distal portion was club-shaped and about the normal size, numerous adhesions stretched across the cecum, burying the white line, and plicating thereby the anterior wall of the cecum. These adhesions were liberated, allowing the cecum to assume its normal shape, etc.

The remarkable improvement following this operation, increase in weight, ability to eat all formerly

shunned foods even as early as his third post-operative day, led me to believe that the suspected calculus was a myth.

About three and a half months later he had a terrific lumbar pain extending to his old appendicular area. This recurred several times. Urine again was examined and blood found. He was submitted to Dr. Caldwell for *x*-ray, with instructions to have his bowels thoroughly empty. Upon this examination a distinct shadow was found in the pelvis of his kidney.

June 7, 1904, he was submitted to a second operation. Israel incision for nephrolithotomy was made, etc. Upon exposing the kidney the stone was found fixed in the terminal portion of the hilum or the beginning of the ureter. This was removed by incising the hilum and simply draining without placing any sutures. A satisfactory although stormy convalescence was made. There have been to date no further abdominal pains nor digestive disturbances.

Case II.—John S., physician, seen in January and February, 1898. For months he had been suffering from typical appendicular indigestion or abdominal disturbances. At the present time he had a sharp attack of pain in the lumbar region simulating renal colic, pain radiating down to within the upper margin of Poupart's ligament.

Diagnosis, renal colic. Stone passed in the latter part of February one and a half inches long. On about March 18 or 20 he suffered from severe abdominal pains higher than usual for an appendix, and considerable digestive disturbance. The pain position with previous calculus history aroused the suspicion of another calculus. No further evidence until March 26, when he was seized with a chill in the morning; pain now absolutely typical of appendicitis; vomited; abdominal rigidity; pulse 114 to 118. Temperature at 6 P. M. 103°. Pain and rigidity well marked. Operation for appendicitis at 8 P. M. Appendix gangrenous. Recovery.

Case III.—M. S., 23, operation November 26, 1904. Six months before consulting me he had an abdominal pain which extended to his back. Three days before my seeing him he vomited, had a severe pain in his abdomen, being bedridden for two days. Some digestive disturbances and another attack of pain which has left him with some soreness in the abdomen, extending up into his right kidney. He also has a very sensitive appendicular region, which extends upwards, resembling somewhat that of an appendix deflected upwards. Advised *x*-ray, although urine was said to be negative.

November 26.—*X*-rayed twice, four plates being taken. In one of these plates a small shadow located at a point opposite the ischial spine in the pelvis was taken for a stone in the ureter. Further physical signs of urine analysis proved negative from a standpoint of stone. Appendicular point pressure on this morning was intensified, and still feeling that there was a stone in the ureter or kidney and that the appendix was also involved, an incision was made beginning at the inner portion of the right rectus extending outwards with a very slight curve to and above the anterior superior spine of the ilium. The skin was then retracted in the course of the rectus, the anterior layer of the sheath of the rectus was cut in the line of the skin incision so that a separation of the muscle fibers of the abdominal wall could be produced. The peritoneum and deep fascia were cut in the axis of the rectus. Exploration revealed a hard nodule more like a gland within an inch of the bladder wall. The appendix was congested and very badly bound by adhesions. This was removed and then the retroperitoneal dissection was made and the ureter exposed, the small body proving to be a stone within the last inch of its course. The ureter was incised in its long axis three-sixteenths of an inch, through which a stone was extruded, two stitches were taken in the coats of the ureter with silk, and the peritoneal wound closed after the kidney had been palpated negatively. Then a drain was put in down to the site of the incision of the ureter, and the wound completely sewed with the exception of the point of the drain. The operation was completed in less than an hour.

The stone is seven-sixteenths of an inch long, five-sixteenths of an inch at its widest point, three-sixteenths of an inch thick, and of an irregular mulberry nature in character.

60 West Fifty second Street

RETRODEVIATION OF THE UTERUS AND TREATMENT BY SHORTENING THE ROUND AND SACROUTERINE LIGAMENTS.*

By C. F. KIVLIN, M.D.,

TROY, N. Y.

The uterus is connected posteriorly to the sacrum by the uterosacral ligaments, whose extensible and resistant fibers are attached to the organ at the level of the cervix. Its connections with the bladder in front and the round and broad ligaments at the side preserve its normal position of slight anteflexion, which it retains as a vestige of its fetal condition. The tonicity of the pelvic floor, of which the only weak point is occluded by the normal contractions of the vagina, prevents the abdominal contents from acting in the direction of their weight; the pressure is distributed over the whole surface and the uterus floats as if it were suspended in the midst of the organs of the lower pelvis which act as cushions for it. When the uterus is artificially drawn downward, this state of the pelvic contents becomes very apparent, for up to the moment when the uterosacral ligaments are stretched and oppose any further descent, the organ yields with but gentle resistance, as of a floating body which is slowly drawn under.

When the bladder is full, it pushes the uterus backward, so that its slight curve of anteflexion is obliterated, to be restored and exaggerated when the organ is again emptied. The rectum, when full, pushes the uterus forward and upward in a corresponding manner, though the physiological condition is seldom so pronounced that its action is noticeable. In case of the bladder, however, it is important, especially as social customs which very quickly become organic habits, exaggerate it considerably. There is but one point of attachment where the uterus is at all firmly fixed, namely, that of the posterior ligaments, and as they are inserted where the organ is thinnest, evidently its position may be compared to that of a pyramid balanced upon its point.

When we consider the extensive change of volume, form, and consistence which the uterus undergoes at each pregnancy; the alterations and lesions which may be produced by parturition on the adjacent organs, ligaments, muscles, and serous membrane; and finally the influence which efforts of all sorts may exert on an equilibrium so unstable, we

*Read at a meeting of the Medical Society of Troy and Vicinity, April 2, 1907.

are surprised that uterine displacements are not more frequent.

Retroversion.—Displacement of the uterus backward is far more frequent than any other variety. Every time that the bladder becomes filled the uterus is placed physiologically in a temporary position of retroversion. The tonicity of the broad, round, and uterosacral ligaments which, it must not be forgotten, contain much muscular tissue, ordinarily sustains the uterus in its normal position; but when it has become increased in weight by inflammation and especially by retarded involution after parturition, the ligaments themselves undergo a relaxation, while the uterus is rendered turgid by metritis, and the abnormal position may become permanent under the influence of prolonged dorsal position.

Then the uterus becomes fixed in the new and abnormal situation by adhesions, the result of a local pelvic peritonitis originating from an inflamed tube which may be the antecedent and chief cause of the whole disturbance. A sudden effort or a fall is often the determining cause of the deviation; retroversion is not so common as retroflexion.

Symptoms. When the displacement has occurred suddenly it is often accompanied by acute pain and various nervous phenomena; when it is acquired slowly, its symptoms are often not to be distinguished from those of a metritis or of a circumscribed perimetritis which may have preceded it, and with these we find the uterine syndrome. Sterility is the rule. Vesical and rectal tenesmus may either be very marked or absent altogether. Palpation and touch recognize the position of the cervix forward and that of the fundus looking posteriorly toward the concavity of the sacrum, where it is more or less immobilized. The two segments of the uterus are found in the same straight line.

Diagnosis. Bimanual palpitation with the rectal touch, and the use of the uterine sound if necessary, are the means by which this form of displacement may be recognized. The distinction from retroflexion is found in the fact that there is no angle in the organ between the cervix and fundus. It should not be confounded with fibroma of the posterior wall, with a retrouterine hematocele, tumor of the ovary or tube prolapsed into the cul-de-sac of Douglas, with the focus of parametritis or with a scybalous accumulation. Almost all cases in which any doubt could exist are easily made clear by the uterine sound combined with other means of exploration; this instrument being especially useful where we must differentiate the condition from anterior cervicocorporeal displacement, which, in view of the direction of its anteroposterior axis, is almost necessarily a source of error if we confine our examination to touching the cervix alone.

Retroflexion.—Contrary to the condition in forward deviations, retroflexion seldom exists from childhood or puberty, although it may follow vaginal metritis, habitual constipation, and masturbation (Fritsch). In the immense majority of cases the retroflexion follows a metritis of puerperal origin, and is due to subinvolution of the anterior face where the placenta is inserted.

Considerable importance must also be attributed to the weight of the congested organ, and to the relaxation of the broad and round ligaments which cease to hold the uterus in place anteriorly, while the cervix remains fixed by the more resistant uterosacral ligaments. The flaccidity of its own supports thus allows the uterus to bend backward at the level of the isthmus, impelled by the weight and pressure of the intestines. Retroflexion has been observed to follow simple retroversion and even anteversion; in the latter case this is possible when the seat of the flexion remains soft and movable like a hinge.

The cervix is directed downward and forward, ordinarily approaching the vulva, for it is usually a little lowered. The external os is somewhat patent and its lips are swollen, owing to the disturbance of the venous circulation which results from the curvature of the vessels. It must not be forgotten that the displacement almost always happens in a woman who has had at some time metritis of puerperal origin. The body of the organ occupies the pouch of Douglas.

Adhesions are often present, either perimetritic from exudation into Douglas' pouch, or parametritic from a similar condition about the uterosacral ligaments. According to the opinion of Schultze, relaxation of the folds or ligaments of Douglas under the influence of posterior parametritis plays a great part in the production of all uterine displacements. In order to comprehend the production of retroflexion we must suppose that during the first stages of acute inflammation the ligaments preserve all their resilience in such a way that the cervix becomes fixed; soon after, in the stage in which exudation retreats, the denutrition of the ligaments causes their flaccidity; then, according as the cervix has resisted or has become flexed in the first stage, we have a retroversion or flexion. In other words, version presupposes alteration in the ligaments; flexion an altered condition of both ligaments and uterine parenchyma together. The peritoneal adhesions fix the uterus to the bottom of the rectouterine pouch, by bands often loose, filamentous, and easily torn. At other times they are funicular, lamellated, and firm. The ovaries and tubes are often drawn by the deviation into the cul-de-sac. It is possible that a part of the nervous reflexes, often grave even to the production of paraplegia, which have been noted in cases of retroflexion, are due to the dragging upon the nerves, and not to the problematical compression of the sacral plexus. Salpingitis often coexists, and is the rule in the irreducible cases, the fact that the organ cannot be reduced very frequently depending upon the presence of adhesions between the adnexa and the walls of the pelvis. Exacerbations of the salpingitis are the cause of these adhesions, and also of the hard, often painful nodules that so rapidly appear and disappear about the lateral and posterior surfaces of the retroflexed organ.

Symptoms. The uterine syndrome is present, the reflex nervous phenomena are very well marked and there is sterility. Constipation, with or without tenesmus, is peculiarly obstinate, and Barnes attributes to this the copremia which so often debilitates the patient. The nervous reflexes appear most often as difficulty in walking markedly out of proportion with that caused by simple muscular fatigue, and simulating paraplegia, as multiple neuralgias hysteriform convulsion, excitability, fitful cough, dyspepsia, and incessant vomiting. Simple straightening of the uterus has caused all these symptoms to disappear rapidly. Sterility is usually the sequence of retroflexion, though at any time fecundation may take place and the uterus return to its proper position. If it remains flexed and incarcerates the fetus in the lower pelvis, it produces serious compression symptoms or abortion. If involution proceeds under the most favorable conditions after labor, the uterus may correct its own malposition spontaneously. That pregnancy in such

cases may be a valuable therapeutic measure can not be denied, and yet its importance has been much overestimated. Certain authors describe a post-puerperal retroflexion in which the displacement occurs immediately after confinement. This is often only one of the symptoms of a post-puerperal metritis with retarded involution, and disappears with the latter under appropriate treatment.

Diagnosis. The tumor occupying the posterior cul-de-sac may, by means of bimanual palpation, be easily recognized as the fundus from the absence of resistance in the anterior pouch where the organ is normally placed, and the possibility of feeling the angle of junction between the cervix and the fundus. Rectal touch is here often indispensable. Exploration with the sound removes the last doubt; it should be curved to suit the axis of the uterus, and the cervix seized with tenaculum forceps and drawn downward.

The uterosacral ligaments are flat muscular bands, which extend from the uterus from the level of the internal os, beneath the layers of the rectouterine ligaments, to the sides of the sacrum, opposite the lower borders of the sacroiliac articulation. In the first part of their course they are in relation with the lateral walls of the pouch of Douglas and finally run on either side of the rectum near the junction of the sigmoid flexure and the upper portion of the rectum.

Deaver, in his anatomy, speaks in the above description of the rectouterine ligaments. The false posterior or rectouterine ligaments, which are composed of peritoneum, are the two serous layers, which pass backward from the posterior surface of the uterus and vagina to the upper portion of the rectum, where they are continuous with the peritoneal coat of the rectum. These folds of peritoneum form the lateral boundaries of the pouch of Douglas. External to each of these false ligaments are found the true or muscular uterosacral ligaments, extraperitoneal connective tissue, and anastomosing branches of the uterine and hemorrhoidal vessels. The round ligament extends from the side of the uterus in front of the cornu; it then passes down between the perimetrium and above the ureter and the external iliac vessel to the internal ring, lifting up the peritoneum as it passes to form a slight investment. It then passes through the inguinal canal, having about the same relation as the spermatic cord of the male.

Treatment. In the treatment it is presumed that all lacerations have been corrected by proper plastic work.

Retroflexion. The round ligament operation may be done as advised by Alexander for retroflexion providing one has a simple uncomplicated case; but if adhesions are present the best thing to do is to shorten the round ligament intraabdominally, where adhesions and pathological products can be clearly seen and dealt with in an intelligent and careful manner and the ligaments shortened by folding and suturing of the round ligament upon itself or to the uterine body. The round ligaments are guiding rather than supporting ligaments and for that reason should never be depended upon to correct a retroversion because they do not lift the uterus up, but guide it forward. It is just this mistake that has made the Alexander operation a failure because of lack of proper application or a mistaken diagnosis of the true condition.

Retroversion. Treatment of retroversion by shortening the sacrouterine ligaments is an operation which is not more difficult than many other operations that have been advanced; and it seems logical to suppose from the numerous operations devised that the profession is not satisfied with correction of this condition. Either from want of confidence or from disappointment with the measure of success which various operations offered, until recently little was thought or known of the supportive strength of the sacrouterine ligaments. To Bovée too much praise cannot be given for his masterly and persistent work in this field of gynecology. The operation has been done as a direct procedure by some operators who reach the ligaments through an incision in the posterior vaginal wall, or from above after opening the abdomen. The object is to draw the cervix backward and upward, thereby restoring the tendency of the uterus to incline somewhat forward as in the normal pelvis, since it is in this position the uterus best resists displacement. For my own part I like the abdominal route the better, because one can then treat any complication much easier and with more confidence than one can from the vagina. A median incision about 2 1-2 or 3 inches is made. The bowels are cleared from the field of procedure. The uterus is then raised from the position with tenaculum and drawn well forward and if the field of operation is clear the sacrouterine ligaments will stand out on each side of the lateral boundary of Douglas' cul-de-sac. The ligament of the left side is attacked by a long chromatized catgut suture. The needle pierces the uterus at the origin of the ligaments, coming out externally on the cul-de-sac side of the ligament. Then grasping with another sweep of the needle enough of the ligament to fold on its origin, with patience one can usually grasp or fold enough to make the necessary shortening; then with one or two reinforcing turns of the needle the operation is finished on that side except that the suture should be left in the needle and clamped outside the abdomen.

The right ligament is treated in the same way as the left, the suture being left long. A suture is then taken in each hand, drawn tight to see if sufficient shortening is effected or if the ligament is shortened on one side more than on the other. When both have been shortened the proper amount for correcting the position, assistant and operator tie the ligaments on their respective sides at the same time.

In the case of both retroversion and retroflexion one has to shorten both the sacrouterine and the round ligaments, the round ligament operation for correction of the retroflexion, and the sacrouterine operation for relief of the retroversion. The combination operation for both displacements is probably the best operation that is offered to the profession at the present time.

TRAUMATIC RUPTURE OF THE SPLEEN WITH REPORT OF A CASE.*

By V. E. Watkins, M.D.

U. S. Army, Fort Greble, R. I.

Rupture of the spleen is of comparatively rare occurrence. It may happen in the normal organ but is relatively much more frequent in the enlarged spleen of malaria, typhoid fever, or the pernicious anemias. If the organ is already enlarged by disease, rupture may appear to be spontaneous, but it is believed that a slight violence may have been overlooked in such cases. Malarial spleens are especially prone to rupture, and for this reason the

*Read by invitation before the Clinton County, N. Y., Medical Society, November 19, 1907.

condition is not infrequently met with in the tropics. Playfair is reported to have seen twenty cases during a residence of two and one-half years in the East Indies. Major Woodruff of the Medical Corps of the Army has reported the case of a Filipino boy who fell while running and died as the result of rupture of an enlarged malarial spleen.[1] In the normal spleen, on the other hand, a considerable degree of violence is required to produce a rupture, such as severe falls or blows upon the abdomen, or crushing of the body by great weight as the passing of a vehicle over it. The organ may be torn in various directions and the tears may be multiple. Usually the capsule as well as the splenic substance is torn and the escaping blood is poured into the abdominal cavity, but the capsule may remain intact with rupture of the pulp alone, the accompanying hemorrhage being into the organ itself. Rupture of the normal spleen, on account of the great violence necessary for its production, is very prone to be associated with the rupture of other abdominal viscera or fracture of the ribs on the left side.

The symptoms are essentially those of an abdominal injury associated with internal hemorrhage. The shock is pronounced, as evidenced by the anxious facies, the pallor, feeble and rapid pulse, and collapse. Consciousness is usually retained in all abdominal injuries.

The pain is severe and may be more pronounced in the splenic region. If the case is seen early before the effusion of blood fills the peritoneal cavity the dullness can be localized in the left flank, otherwise it will be general over the abdomen. An unusually pronounced contraction of all the abdominal muscles has been reported as a diagnostic sign, but it does not occur in all cases and cannot be considered pathognomonic. In fact it may not be more marked than in other abdominal conditions. Vomiting may or may not occur.

From this résumé of the symptoms it will be seen that they are essentially those of internal hemorrhage, and the diagnosis is usually not made until after abdominal section. The symptoms are obscure so far as enabling us to differentiate whether the spleen or some other abdominal viscus is ruptured. However, there should be no difficulty in diagnosing the existence of hemorrhage into the abdominal cavity, and when this condition is recognized, abdominal section is indicated. The incision should be made over the region of greatest dullness, if this can be determined. If percussion elicits a note of higher pitch in one flank than in the other, a valuable hint as to the source of hemorrhage has been obtained. Should the hemorrhage be sufficiently severe to give a percussion note of equal dullness in all regions the indication is to make the incision in the middle line.

The treatment is essentially surgical, the object being the control of hemorrhage, and all authorities are agreed that this end is most certainly accomplished by splenectomy. The mortality following removal of the healthy spleen for rupture is about 40 per cent., whereas that of non-operative treatment is probably 100 per cent. Ligation of the bleeding vessels has been recommended, but is invariably followed, in animal experiments, by necrosis. Control of the hemorrhage by suture has been advised and has succeeded in some cases, but in the large majority the sutures have failed to control the hemorrhage and the patients have died. Tamponade is certainly a quicker and better method than suture, according to the results thus far published, yet some authorities reject this treatment as suitable only when the tear is small, or in cases in which the condition of the patient necessitates a speedy ending of the operation, or in those in which extensive adhesions make the removal of the spleen too long an operation.

Flammer[2] reports three cases of splenectomy for rupture, with two deaths. One of these patients was not operated on until the third day, and besides the rupture of the spleen there were fractures of four ribs and a pancreatic rupture. In the other fatal case operation was not performed until the fifth day and was followed by peritonitis and double pneumonia. These fatal results are arguments for prompt surgical treatment rather than against operation. Whatever operation is decided upon it should be done promptly, expeditiously, and with every expedient calculated to relieve and prevent shock.

The question naturally arises what are the effects upon the animal economy of removal of the spleen? According to Ehrlich, to whom we owe much of our knowledge concerning the blood, there is a great increase in the number of leucocytes after extirpation of the organ, with a marked hypertrophy of the lymph glands of the body. These blood changes do not extend beyond a period of four or five months. There is no evidence that the removal of the spleen has been followed by a death which could be attributed to the loss of the organ. Many patients have lived for years in good health without it, one for twenty-three years.

Gerrard[3] cites a case of rupture of the spleen recovering under medical treatment. A four-year-old Chinese boy was run over by a carriage, the wheel passing across the lower part of the chest. The symptoms were hemoptysis with frothy expectoration, rapid and feeble pulse, and shock. There was dullness over the lower portion of the left chest and in both flanks. The patient's condition was not favorable for abdominal section. The treatment consisted of the administration of ten-drop doses of fluid extract of ergot and the same quantity of tincture of opium every hour, until the patient was well under the influence of the opium. Ice was applied to the left chest and abdomen and an eight ounce saline enema was administered every hour. Fluid by mouth was given four and one half hours after the accident. The patient made a good recovery. The dullness in the right side of the abdomen disappeared in five days, but the area of splenic dullness was still enlarged 24 days after accident. Many surgeons are inclined to question the diagnosis of rupture of a viscus when a patient recovers from a severe abdominal injury without operation.

The present case is as follows: E. P., a civilian, age 23 years, was at work on the morning of May 6, 1907, with two other men, on a scaffolding about nineteen feet high, putting in place a lintel weighing about 300 pounds. The staging broke and the men were all thrown to the ground. The patient was found pinioned to the side of the building by the lintel. He was suffering severely from shock and was admitted to the Post Hospital, Plattsburg Barracks, N. Y., at 11 A. M.. Examination elicited the following points: shock pronounced; pulse rapid and feeble; respirations rather shallow and hurried; expression of face anxious; moderate distention of the abdomen; severe pain in the abdomen, particularly on left side, and aggravated by pressure; rigidity of the abdominal muscles slightly greater on left side; there was marked dullness on percussion over the splenic area and extending well down into the left flank. A diagnosis of hemorrhage into the abdominal cavity was made, and laparotomy performed at 4 P. M.,

about six hours after the accident. The incision was made over the area of dullness and extended from the lower costal border on the left side downward to a point midway between the umbilicus and the anterior superior spine of the ilium. Upon opening the abdominal cavity a large quantity of fluid blood and clots were found. Palpation of the spleen showed a tear extending deeply into the anterior border of the organ. The patient at this time was in such a precarious condition that no further operative procedures were warranted, and the use of tampons was decided upon. The fluid blood and clots were removed from the abdominal cavity and four thick strips of iodoform gauze were packed tightly into the torn spleen, and the abdominal incision was partially closed at the lower end. The bleeding was profuse for several hours after the operation, saturating the dressings and soaking the draw sheet under the patient.

The next morning, May 7, the bleeding from the wound was considerably less, but still alarming, the pulse was very rapid and feeble, expression anxious, respiration shallow, thirst intense; there was great restlessness and the extremities were cold—the symptoms of exsanguination. The abdomen was greatly distended and painful, and vomiting was almost incessant. Morphine hypodermically in one-eighth grain doses was used to control pain and restlessness. Normal salt solution was administered per rectum every two hours, with an ice bag to the abdomen. On May 8 the patient's condition was much improved. The hemorrhage had stopped, the bowels moved voluntarily, and the tympanites was less. Vomiting continued, but was not so frequent as on the day before. The pulse was of better quality and not so rapid. A nutrient enema was given every four hours. On May 9 the improvement was more marked; the bowels were quite loose, the pulse good, and the vomiting entirely stopped. During the afternoon milk was given by mouth in teaspoonful quantities and retained. On May 10 the patient remarked that he felt good, the tympanites had about subsided, and milk was retained. Following the operation the temperature reached 100° in the axilla and was normal on the evening of the 12th. The pulse followed the normal ratio of the temperature curve. On the 13th, one week after operation, the four tampons were removed from the abdominal cavity, under chloroform anesthesia. Only a slight oozing followed. The abdominal wound closed by granulation and the patient left the hospital June 19. He returned a few days afterward with a large ventral hernia for which he declined operation.

RELAPSING FEVER WITH A REPORT OF TWO CASES.

By SAMUEL J. GOLDFARB, M.D.,
NEW YORK
HOUSE PHYSICIAN, BETH ISRAEL HOSPITAL.

Although relapsing fever has been known since the days of Hippocrates who observed an epidemic in the Island of Thasos, it was not until 1873 that the true cause of this disease was made known. In that year Obermeier announced his discovery of the presence of a minute parasite in the blood of patients suffering from relapsing fever. His observations were subsequently confirmed by Carter in 1876, and by numerous observers in various parts of the world. It is the first infection in which a microorganism was found to be causal. This discovery has thrown a flood of light upon the etiology of relapsing fever, and is one of the most significant facts, with reference to the etiology of infectious diseases in general, which have been brought to light by modern microscopical researches. Strange to say, no references to this fever seem to have been made from the time of Hippocrates until Strother, in 1729, described an epidemic in London of a disease with relapses. Rutty in 1739, described its occurrence in Dublin. Since then, similar observations of epidemics in Ireland and Scotland were noted toward the end of the 18th and beginning of the 19th centuries. In 1801, 1817 and 1819, Barker, and in 1826 Obrein and Graves described similar epidemics. For some time this disease was confounded with typhoid and typhus fevers. Henderson in 1842, Jenner in 1849 and 1851, and Murchison in 1862, had an opportunity to make a thorough study of the disease, during epidemics in these years in England, Ireland, and Scotland, and as a result of their labors it was recognized as a disease independent of typhoid and typhus. All the epidemics occurring in Great Britain emanated from Ireland.

The disease next appeared in Russia; in 1833 in Odessa; in 1840-1841 in Moscow. In 1863-1865 a great epidemic raged in St. Petersburg; in 1865 in Siberia, reappearing later in these and other places in Russia. It occurred extensively among the soldiers in the Russo-Turkish war. In Germany it first appeared in Silesia in epidemic form, in 1847 to 1848. In 1868-1873 large epidemics occurred throughout Germany and it was during these epidemics that Obermeier discovered the spirochetes in the blood. The disease has also frequented nearly all of the other European countries. In India it also appeared in epidemics, the most important of which was in Bombay and vicinity in 1876 and 1878. This epidemic permitted Carter, who had made a careful study of this disease, to confirm the observation of Obermeier with reference to the spirillum. About the year 1850 Griesinger observed in Egypt, particularly in Cairo, relapsing fever in connection with bilious-typhoid and typhus. Engel's studies in Cairo in 1884 also corroborated the observations of Obermeier. In the United States it was first heard of in Philadelphia, where it was imported by Irish immigrants in 1844, and recognized by Clymer. In 1847 it was observed in New York City, and from here spread to neighboring towns. In 1850 Flint saw some cases in Buffalo. in 1870 it reappeared in Philadelphia and again at the same time in New York City, always among Irish immigrants. During the hot summer of 1870 five thousand cases were reported in Philadelphia and New York City and the neighboring towns. In 1874 it appeared in California, but from this time until 1905 this country was free from relapsing fever, when Carlisle reported two cases in Bellevue Hospital.

The spirochetes are wavy, motile fibrils tapering to a point varying in length from one-half to ten times the diameter of a red blood cell. They are homogeneous protoplasmic masses in which no structure has been observed; the number of turns varies from eight to twenty. The organisms are not found in any fluid of the body except the blood, and here only immediately before, and especially during the febrile stage of the disease. Some observers, among them Heidenreich, have noted their appear-

ance in the blood, several hours to a day before the beginning of a paroxysm. As soon as the crisis approaches, the organisms lose their motility and disappear from the blood. Only in exceptional cases has their presence been noted in the blood during the apyretic period. The number of spirochetes in the blood on successive days of the paroxysms is steadily on the increase, until it reaches the maximum 24 hours or so before the crisis occurs, from which time the number of organisms begins to decrease, so that within a half hour after the beginning of sweats, the spirochetes have completely disappeared from the blood.

The probable cause of the disappearance of the spirilla from the blood during the apyrexial stage is as yet unexplained. Metchnikoff believes that they are largely, if not altogether, destroyed by the phagocytes which engulf them, and carry them to the spleen. This organ becomes enlarged and is the seat of the chief pathological changes in those cases in which death from the disease occurs. It is then seen to be filled with white blood cells containing the parasites.

Ivanoff and Gabritchewsky believe that some substances appear in the blood that possess parasiticidal powers, which destroy the spirochetes. If we add to blood containing spirochetes, some blood taken from a patient who has just emerged from a paroxysm, we shall see in a period of from one to four hours, all the spirochetes become immobile, change form, and die.

Ivanoff inoculated with blood taken from a patient suffering from relapsing fever, some monkeys, among which were several that had previously received an injection under the skin of blood taken from a person who had just passed through an attack. While the control animals exhibited in a few days the characteristic symptoms of the disease, those which had received the preventive inoculation escaped with a fever of moderate duration, unaccompanied by the presence of spirilla in the blood.

Metchnikoff, according to his theory of the disappearance of the spirilla from the blood, as mentioned above, gives the following explanation as to the cause of the relapse. He has shown that after the parasites have disappeared from the blood, masses of them may still be present in the spleen, where they are mostly enclosed in cells many of which seem to be undergoing degeneration, and it is possible that the contained bacilli may then escape in a condition capable of causing a relapse, or those microbes which have not been engulfed may be responsible for the second febrile attack.

As yet, no media have been discovered suitable for the cultivation of the spirochetes, nor have we as yet discovered their mode of reproduction, whether by segmentation, sporulation, or otherwise, although recent researches tend to show that it most likely occurs by transverse division.

As yet, the exact mode of transmission of this disease is not known; neither food nor water, air, nor earth, can be held responsible *per se* for the transmission of relapsing fever. Poor hygienic surroundings predispose to attacks. It is probable that the ordinary parasites of man play a more or less important rôle in spreading the contagion by carrying the blood from one to another. The contagiousness of the disease is quite marked, 40,000 persons having been attacked in Dublin in 1847-1848. Inoculation experiments in man have proven successful. Metchutkoffsky of Odessa, in 1873, had an opportunity to inoculate a number of human beings with the disease. Inoculation experiments in animals have been negative, except for monkeys and recently in mice and rats. Ticktin examined bedbugs which had bitten man and monkeys with the disease, and found that the blood of these bugs contained spirochetes.

One attack does not confer immunity. Christison suffered from three attacks in fifteen months. According to Metchutkoffsky, immunity lasts for two weeks only. Carter and others were able to produce a second infection in monkeys.

On August 2nd, 1907, two patients, a mother and daughter, were admitted to Beth Israel Hospital in Dr. Barsky's service, with a diagnosis of typhoid fever.

The mother gave the following history: Age 40, born in Russia. Housewife. Family, personal, and past history have no bearing on present trouble.

The present illness began suddenly two days before admission, the patient having felt perfectly well until the noon of that day, when she had a chill followed by profuse sweating and very high fever; severe headache, referred mainly to the occipit and vertex; anorexia; nausea and vomiting; general muscular pains, especially in muscles of back and limbs; general weakness; constipation; abdominal pain and insomnia; no epistaxis; no respiratory, renal or cardiac symptoms. The daughter, 9 years old, school-girl, gave a history almost identical with that of her mother, but her disease was not so severe and began one day earlier.

The following is of etiological importance in our cases: W. S., a distant relative coming from Russia, boarded a transatlantic steamer in Antwerp, on which he was taken ill when four days out, with following symptoms: High fever; anorexia; nausea; vomiting; sweats; restlessness; headache and general muscular pains, which were attributed to seasickness. He was sick five days, felt well for the last two days of his journey, landed in this city, and stayed with our patients. After remaining well for six days, he again took sick with symptoms similar to above; was sick for five days and then left their house. On the following day the daughter, and two days later the mother became sick.

Case I.—On admission, the mother's rectal temperature was 105.6°, pulse 138, respiration 32. General condition fair, fairly well nourished, no eruption; skin hot and dry; cheeks flushed; tongue dry and heavily coated with a grayish fur; throat examination negative; glands palpable in axilla and groin; lungs showed the presence of a few sibilant and sonorous râles. The heart sounds were somewhat weak, regular, no murmurs, no accentuations. The pulse very rapid; regular in force and frequency; of low tension and with a slight thickening of the arterial walls. The abdomen was distended and tympanitic, tender in the splenic area; no rigidity; in liver dullness began in the fourth space, flatness in the fifth space, extending to just below the free border of the ribs; edge indistinctly palpable; the spleen was palpable one finger's breadth below the costal border, and was tender. There was marked tenderness in the calves of the legs. Blood examination: White corpuscles, 14,800; polynuclears 74 per cent.; large lymphocytes 10 per cent., small lymphocytes, 16 per cent.; examination for plasmodia negative; widal negative. Urine: Specific gravity 1006; acid; heavy trace of albumin; no sugar; no diazo; few granular casts.

August 5: For the past two days, the temperature has ranged between 103° and 105°, pulse between 120 and 134. General condition about same as on day of admission. Spleen and liver have increased in size. At 3 A. M. the temperature dropped

from 104° to 98°, accompanied by drenching sweats, general abdominal pains, and profuse diarrhea. The pulse dropped from 136 to 100.

August 6: Patient felt very much improved.

August 8: Patient well enough to be out of bed. Temperature remained normal. Pulse averaged about 80. The leucocyte count had gone down from 14,800 to 8,200. Widal, still negative.

August 12. After the temperature had remained normal for seven days, it gradually began to ascend this morning, reaching 102° in the evening. This rise was accompanied by chilly sensations, headache, pain in the abdomen and lower extremities, and severe tenderness in the calves. Restlessness and nausea were marked. The above symptoms compelled the patient to take to bed.

August 13: To-day, temperature reached 104°, pulse rose from 84 to 116, and the above symptoms became more intense. It was at this time that relapsing fever suggested itself, and a thorough search for spirochetes was made, and to our great surprise, spirilla in large numbers were found in the blood of both mother and daughter.

August 14: This morning the temperature dropped from 104° to 101° and rose in the evening to 106°. The woman vomited everything taken by the mouth. Tongue dry and coated; headache very severe; prostration marked; pain and tenderness in calves, a prominent symptom. Liver and spleen had increased in size. Spirochetes present in large numbers. White blood count 18,000.

August 17: At 9 A. M. the temperature began to drop and by midnight, it had fallen from 104° to 96°, accompanied by a distinct chill of 20 minutes' duration, during which the patient vomited, had profuse diarrhea, and was markedly delirious. The chill was followed by profuse perspiration. Blood examination that morning showed the presence of spirochetes; in the evening they had disappeared from the blood.

August 18: On this day, the patient felt much better; temperature between 97° and 98°; all symptoms markedly improved; white blood count 9,400; spirochetes not found in the blood; liver and spleen diminished in size.

August 21: General condition much improved; patient out of bed; put on a full diet; all symptoms disappeared; liver and spleen not palpable.

August 31: Patient discharged entirely cured.

CASE II.—On admission, rectal temperature was 105.4°; pulse 128, respiration 36. General condition fair; fairly well nourished, but anemic; face flushed; no eruptions; no jaundice; tongue moist and heavily coated with a whitish fur; pharynx and tonsils congested; glands palpable in axillary, submaxillary, and inguinal regions. Lungs negative. Heart showed the presence of a double mitral murmur. Pulse small, regular in force and frequency; fair tension. Liver dullness begins at fifth rib; flatness at sixth rib and extends to just below the free border of the ribs, where the edge is palpable. The spleen is palpable one finger's breadth below the free border. Blood examination.—Red blood count 4,000,000; hemoglobin 70 per cent.; white blood count 12,000; polynuclears 51 per cent; large lymphocytes 18 per cent.; small lymphocytes 31 per cent.; widal negative; plasmodia negative; urine showed a faint trace of albumin.

August 4: After remaining in the vicinity of 106° for the past twenty-four hours, the temperature began to drop last night at 9 o'clock, and by six o'clock this morning had fallen to 96°, a drop of 10 degrees. The pulse decreased in frequency from 140 to 84, and the respirations from 32 to 24. Accompanying this was a slight chill, profuse perspiration; retention of urine; marked restlessness. In the afternoon of the same day the patient felt very much improved.

August 7: For the past three days, the temperature has ranged between 97° and 98°; general condition very much improved; no pain or tenderness anywhere; spleen still palpable; the patient is out of bed.

August 12: After the temperature had remained normal for the past eight days, it gradually began to rise this morning and reached 102° in the evening.

August 13: To-day the temperature reached 104.8°; pulse rose from 84 to 128; at the same time the girl experienced a feeling of malaise, severe headache; anorexia and indefinite pains throughout the entire body. The above symptoms compelled her to take to bed. Spleen and liver were palpable. As mentioned before, it was at this time that relapsing fever suggested itself and spirochætæ were found in the blood.

August 14: For past two days, temperature ranged between 104° and 106.4°; the symptoms were the same as on previous days. Liver and spleen had increased in size. At 6 o'clock this evening the temperature began to fall, and by the following night it had dropped to 95°, a drop of 11.5°. The pulse slowed down from 132 to 72. Accompanying the drop, the patient felt very cold, perspired profusely, was nauseated and very restless. Liver and spleen still enlarged.

August 17 and 18: For the past two days the temperature has remained subnormal; general condition much improved; spleen and liver decreasing in size. Weakness is the only complaint.

August 21: Temperature normal; liver not palpable; spleen can be felt just below free border of ribs.

August 31: Discharged perfectly cured.

Treatment:

The treatment can be summed up in a very few words: 1. Isolation; 2. Symptomatic. There is no drug which in any way influences the course of the disease. The symptoms are treated as they arise: (*a*) Fever—as in typhoid; (*b*) Diarrhea, bismuth, tannigen, and opium; (*c*) Pains, phenacetin; antipyrin; chloral; massage; (*d*) Headaches will be relieved by above drugs aided by an ice-cap. 3: Specific. In 1895 Gabritschewsky produced a serum by injecting blood containing spirilla into horses. He tested this serum upon monkeys with success. In 1896-1897, Lowenthal used the serum in Moscow, treating 152 patients with excellent results.

I take this opportunity to thank Dr. J. Barsky, Visiting Physician to Beth Israel Hospital, for permitting me to publish these cases, and the members of the house staff for their hearty cooperation in working up these cases.

An Unusual Distinction.—In a small New Jersey village a centenarian has been discovered who has a great granddaughter who is herself a great grandmother, that is, she is the head of seven living generations. She lives with her daughter of eighty-four and a granddaughter of sixty-seven.

Mortality of Bull Fighting.—During the past year deaths and injuries among the Spanish bull fighters have been unusually numerous and in all eighty-two of the profession, including nearly all of the best known espadas, have received more or less severe injuries. The mortality among the animals has also been exceptional, 2,980 bulls and 2,720 horses having been sacrificed in this way.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THERAPEUTIC OPTIMISM.

"GOOD practitioners are always found to be men entertaining the greatest confidence in the power of medicines." This truism was uttered by Roberts Bartholow in an address delivered before the Medical and Surgical Faculty of Maryland in 1876. Unfortunately for the science of therapeutics this great teacher died and his teachings were nearly forgotten. Twenty years later a prominent member of the same society was preaching the doctrine of black nihilism, of expectant treatment, and of self-limited diseases. He was a good pathologist and an acute observer, though self-confessedly a poor practitioner, but he possessed unusual power of literary expression through which he attracted so large a following that for a time it seemed that America would wrest from Germany the ignoble distinction of being the home of therapeutic pessimism. This preacher of despair did not die, but he has been translated, and only now and then a feeble echo of his pessimistic aphorisms is carried to us by cable and wireless telegraphy; but it is now *vox et præterea nihil*, the blight on American medicine is removed, and once more the voice of therapeutic reason and common sense is heard and is listened to.

At the recent meeting of the Medical Society of the State of New York Dr. A. Jacobi delivered an address, entitled "Nihilism and Drugs" (*New York State Journal of Medicine*, February, 1908), in which he sounded a note of optimism most cheering to those who believe that the mission of medicine is to relieve suffering and save life, and that the study of pathology is only a means to an end, and not the sum and substance of medical endeavor. In his opening, the speaker referred to Osler's recent address to London students in which he warned them to "be skeptical of the pharmacopeia" and said that "he is the best doctor who knows the worthlessness of most drugs." Dr. Jacobi charitably endeavored to explain away these smart sayings by interpreting "skeptical" in the sense of "examine and test," but we suspect he knew and knew that his hearers knew that the Regius Professor meant just what he said, and that he is still the incorrigible nihilist who continues to lay the blame upon drugs for his inability to use them.

Expectant treatment, Dr. Jacobi said, is too often a compound of indolence and ignorance, and he cited numerous illustrative cases where patients who had been condemned to death or a protracted invalidism were saved and restored to health by timely medication. "Expectant treatment! Verily I tell you, it is malpractice, which shall be punished on account of neglecting what nature and sound therapeutics furnish. . . . Expectant treatment is no treatment. It is the sin of omission, which not infrequently rises to the dignity of a crime." These words are the words of wisdom and of truth; they should be printed on tablets in letters of gold to remind every practitioner of his duty whenever he is tempted to shirk it. Disease, whether "self-limited" or unlimited, is the enemy which the physician is sworn to attack, and he is a coward or a weakling who skulks in his tent while the enemy is gaining force.

There is a good old-fashioned ring to this address of Dr. Jacobi which will bring cheer and encouragement to the practitioner who has gone his way treating the sick as he was taught in his early days of long ago, giving homely drugs and plenty of them, when need there was, but stealthily almost lest he should incur the ridicule of his younger brethren indoctrinated with therapeutic skepticism and scornful of the "unscientific" methods of the past. Digitalis, strophanthus, spartein, camphor, caffeine, strychnine, ammonia, musk in pneumonia; extract of belladonna in doses of half a grain to a child of four years suffering from enuresis; one-fourth of a grain a day in divided doses of corrosive sublimate to an infant with diphtheria; daily doses of two drams of iodide of potassium to a baby with tuberculous meningitis; opium in doses of one-fortieth to one-thirtieth of a grain every two hours to a child a year old suffering from enteritis; emetics, purges—these are some of the drugs which the speaker had the courage to declare he used when he met the indications for them, and used with good effect. The prejudice against polypharmacy—shotgun prescribing the one-drug man or the no-drug man calls it—was also combated. "There are those," Dr. Jacobi said, "who dislike a prescription blank filled with three or four remedies, but there are also those who dislike the looks of a patient whose many ailments should not have to wait for the gradual and slowly conservative administration of drugs that could as well act simultaneously and conjointly, and better when conjointly. . . . The disease of an adult has a long anamnesis and the residue of previous illnesses. By insisting upon giving a single remedy, you may care for and cure the last affection, and let your patient slip away from you under expectant treatment."

Does the man who preaches nihilism ever think of the consequences of his teaching? Does he ever think that the men, his equals at least in intelligence and honesty, who believe in the power of drugs and who claim to get good results from their use of them, may possibly be right? Does he ever admit to himself, in signing his death certificates, that his failure may be due to ignorance and a lack of ability to use the tools of his calling? Drugs may not always produce the results expected; they may, when injudiciously employed, even do harm; there are few specifics, and these few do not always cure. But they are potent weapons, in skilled hands, in the combat with disease, and the man who despises them or knows not how to use

them, has no right to call himself a physician or to attempt to practise medicine. There is a field for his abilities in the laboratory, but he should take his hands off the sick, and not abuse the trust they place in him by abandoning them to the processes of nature which are so often misdirected. Dr. Jacobi's address is an eloquent protest against this baleful doctrine of the inefficiency of drugs. It will probably fail to break down the conceit of the therapeutic nihilist—may his shadow grow less—but we commend its careful study to the young practitioner whose first unsuccessful essays in treatment may tempt him to regard all drugs as useless and the materia medica as a relic of superstition.

THE TREATMENT OF GASTRIC ULCER.

At a recent meeting of the Leeds and West Riding Medico-Chirurgical Society held at Leeds (*Lancet*, February 15, 1908), a discussion on this subject was conducted by Dr. A. G. Barrs and Mr. B. G. A. Moynihan. This discussion was notable for the reason that Dr. Barrs propounded some iconoclastic views as regards the diet of patients suffering from gastric ulcer. Although, of course, in favor of a simple diet, he never ordered milk for such patients, and he utterly repudiated the old practice of saying to a patient with gastric ulcer, "A milk diet or your life." He wished one could see the same reduction in the milk bills of the hospitals as one had seen in recent years in their alcohol bills. He could not understand how members of the profession could go on countenancing milk drinking in bulk by adult patients and the public at large, knowing as they did that it was probably the surest way of introducing the tubercle bacillus as well as other pathogenic organisms into their bodies. He considered that bulk was a much more important matter in the food of a patient suffering from gastric ulcer than kind, and small meals of meat and stale bread—if these could be taken without pain, but not unless—along with water in any reasonable quantity to drink, was the food that he usually suggested; but if there were vomiting, no food should be given, only plain, fresh water to drink. Dr. Barrs likewise inveighed in strong terms against the employment in the dietary of a patient with gastric ulcer of any form of artificial or artificially digested food, or of any of the so-called digestives. Patients, he said, suffering from recent and severe hematemesis were never hungry and therefore did not require food. After three days from the cessation of the hematemesis, food such as meat, eggs, and stale bread might be given if the patient wished, but not otherwise.

Up to a comparatively recent period milk was regarded as the "sheet anchor" in cases of gastric ulcer, or, indeed, in any cases in which irritation of the intestinal tract was present. Sir William Jenner's great reputation as a physician rested, to some extent, upon his well known dictum that a milk diet was indicated invariably when typhoid fever was present. Anyone who had ventured, say twenty years ago, to dispute this view would have been regarded as indiscreet and would have found few, if any, supporters. Now the pendulum appears to be swinging in another direction. Dr. F. Smith, physician to the London Hospital, has for two or three years caused patients under his charge suffering from typhoid fever to be fed with meat, abjuring milk. Dr. Smith read a paper on the subject at the meeting of the British Medical Association held in Toronto in 1906, and showed from statistics that his results were, at least, as good as the results of physicians who kept to the time-honored milk diet for typhoid patients.

Many other medical men in various parts of the world have deviated from milk as the sole or even main food for individuals suffering from typhoid, and it does not seem that the death rate from that disease has exhibited any increase, in fact there has been a decrease in the mortality rate. It may be safely argued then that milk is, at any rate, not the only diet for typhoid patients. Dr. Barrs' strictures on milk, however, go much further; he utterly repudiates the use of milk for persons with gastric ulcers, an opinion which many will adjudge too radical. It has yet to be conclusively proved that milk is harmful in cases of gastric ulcer, although it would appear that too much milk, as too much food of any description, would not be suitable for such cases. There is no doubt that bulk in diet is more likely to do harm than kind, but it would be curious if milk were to lose favor with physicians as a food for sick persons. This would be indeed a swinging of the pendulum.

Dr. Barrs' remarks as to the danger of infection by means of milk reflect the present trend of medical opinion. A strong prejudice has been created against milk in all parts of the civilized world on account of the knowledge that many diseases are spread by contaminated milk. Public opinion has been aroused with the result that in all large towns the milk supply is being closely scrutinized and efforts are being put forth to ensure a fairly pure milk for general consumption. Given a milk free from pathogenic bacteria it cannot be denied that it is after all the best food for young children, for a goodly proportion of the sick, and, in spite of Dr. Barrs' animadversions, even for those suffering from gastric ulcer, when it is used with discretion.

The Process of Repair After Pubiotomy.

At the meeting of the German Gynecological Society held in Dresden last year the chief topic for discussion was the operation of hebeosteotomy, as the procedure of dividing the os pubis to facilitate delivery is now beginning to be called. Particular interest was taken in the question as to the ultimate condition of the bone wound, whether bony union took place or only a connective tissue growth, and if the latter, whether at subsequent pregnancies this was likely to stretch enough to permit unaided delivery. So far the only information available in regard to these points has been afforded by the numerous Roengen ray examinations that have been made at varying times after the operation and which have led to the assumption that while at first fibrous union occurs, this is later on replaced by true bone. As the question is one of considerable importance in estimating the advantages of, and the indications for, the operation, the report of what is probably the first autopsy record of the conditions existing some time after the division of the bone will be received

with much interest. Oberndorfer in the *Zentralblatt für Gynäkologie*, February 15, 1908, describes what he found in the case of a woman dying of an intercurrent affection fourteen months after successful hebeosteotomy which left no limp or other disability. The line of incision in the bone was on either side surmounted by bony ridges and the first radiograph made gave a picture that seemed to indicate that the union was of bone. On turning the specimen slightly, however, and making a second exposure, it was shown that the first result had been deceptive and that a line of fibrous tissue was clearly visible. On microscopic examination the gap, which measured 2 mm. in width, was seen to be filled with extremely dense fibrous tissue, with a thin layer of cartilage cells at either border, but there was no evidence of any attempt at metamorphosis of this tissue into bone, while the manner in which the everted edges of callus at either side had become ossified seemed to indicate that the fibrous tissue offered an insuperable barrier to further bony change. Oberndorfer therefore believes that the radiographs in previous cases have been misinterpreted and that fibrous union is the usual course of events after this operation. The reason for this failure of bony union is probably to be found in the smoothness of the sawn surfaces as opposed to the splintering and irregularity following a fracture, with its attendant greater stimulus to, and opportunities for, new bone formation.

Von Pirquet's Cuti-Reaction in Tuberculosis.

The reaction following cutaneous inoculation with tuberculin has not been so widely tried as its modification, the ophthalmo-reaction of Calmette. Yet the earlier method possesses one great advantage over its modification in being quite free from all danger to the patient, while the introduction of tuberculin into the conjunctival sac has in a few instances been followed by destructive inflammation of the eye. Moreover, neither the relative nor the final value of these new diagnostic methods can be considered as settled, and careful observation of them, especially in institutions where frequent autopsies are performed, is of great interest. Of such character is the work done by Drs. F. C. Kopetz and S. M. Sembjusky in the Infant Asylum of Warsaw (*Gazeta Lekarska*, January 18 and 25, 1908). They tried the cutaneous reaction in 251 cases, 198 of which were of infants under one year of age, while the ages of the remaining fifty-three patients ranged from one to ten years. Only two children of the first group gave a positive reaction to the test, yet four of the thirty-five cases that came to autopsy showed tuberculous infection. One of these cases gave a positive reaction during life. Fourteen children of the second group showed a positive reaction, four cases of undoubted tuberculosis, clinically, not reacting. Of the six cases in this group that came to autopsy two cases of tuberculous infection were discovered that did not react to the test. These figures justify the conclusion of the authors that the clinical value of the cutaneous reaction is not very great, though there is an undoubted relation between the reaction and tuberculosis. A negative result especially cannot be depended upon, but we are forced, by the results of trials of the method by these and other observers, to the conclusion that even a positive reaction to the test cannot be considered as proving the presence of tuberculous infection.

Tuberculosis in Infancy.

One of the most striking features of the observations that have been accumulating on the subject of tuberculosis during the early months and years of life has been the demonstration of the great susceptibility of infants to the infection and of the very inadequate means of defense possessed by the immature body. Sehlbach, for example (*Münchener medizinische Wochenschrift*, February 18, 1908), goes so far as to say that when once a tuberculous focus has appeared in an infant the latter is destined sooner or later to die of the disease, a dictum somewhat at variance with the view of von Behring, who regards more or less permanent latency of such lesions as a not infrequent occurrence. Sehlbach's conclusions are based on the records of 1,423 autopsies on children under the age of nine years performed in the Breslau children's clinic during the past ten years. Of this number 1,157 were on infants less than a year old and the total number of cases of tuberculosis was 180. The figures show that during infancy the mortality from the disease does not increase from month to month, but that there are two distinct periods of remission toward the end of the first and of the second year. The two chief times of infection would appear to be during the first three months, the so-called cradle infections, and during the latter part of the first and the beginning of the second years, the so-called dirt or creeping infections. A very clear demonstration of the protective power of breast feeding is also afforded, for the greatest number of deaths occurred among the bottle-fed infants and a large number among those who were on mixed feeding, while the breast-fed children were in the minority.

News of the Week.

Leprosy in the Canal Zone.—A colony for lepers has been established at Palo Seco, a spot not far from Panama and overlooking the bay. Eight new buildings have been provided for the seventeen patients and their attendants. When the Government took charge of the canal construction there were eleven persons with leprosy huddled together in a building on the outskirts of the City of Panama, where they were nominally under the care of the Government of Panama, and several other lepers were scattered throughout the zone.

Smallpox in Rome.—Owing to ill-advised attempts to conceal the presence of a few cases of smallpox in Rome in order not to keep away tourists, exaggerated fears as to the severity of the outbreak have become prevalent and the city is in a state of great alarm. For a time the supply of vaccine was exhausted, and many people made preparations to leave the city.

Scarlet Fever at Newington.—A small epidemic of this disease is reported from the Home for Incurables at Newington, Conn., and a number of the patients have been removed to the Hartford Hospital.

Yellow Fever in the West Indies.—Mexican ports are enforcing a thirteen days' quarantine against Havana and a strict quarantine is also in force in Jamaica. Barbadoes and Trinidad are now said to be entirely free from yellow fever.

Milk Supplies and Infectious Diseases.—Surgeon-General Walter Wyman of the Public Health Service has submitted to the Secretary of the Treasury a "Report on Milk in its Relation to Public

Health," which, among other matter, contains the details of five hundred epidemics of typhoid fever, scarlet fever, and diphtheria definitely traced to the milk supplies of the affected districts. Of this number three hundred and seventeen were typhoid fever, one hundred and twenty-five scarlet fever, fifty-one diphtheria, and seven pseudo-diphtheria epidemics.

Atomic Weight of Radium.—At a recent meeting of the Royal Society in London Dr. Thorpe, the director of the government laboratory, made the announcement that as the result of his experiments it appeared that the atomic weight of radium was about 227, taking hydrogen as the standard.

Prizes of the International Tuberculosis Congress.—The central committee of the congress announces the offer of prizes in eleven classes of subjects connected with the prevention of tuberculosis. One of the prizes is $1,500, five are of $1,000 each, and the others consist of smaller sums of money and medals. The chairman of the committee on prizes is Dr. Charles J. Hatfield, 258 S. 18th street, Philadelphia, Pa.

Philadelphia College of Physicians.—The contract for the new building of the College of Physicians, of Philadelphia, to be erected at Twenty-second and Ludlow streets, has been awarded and work is to start promptly. The estimated cost of the structure is $300,000, and it will be a two-story fireproof building 110 by 150 feet, containing a lecture hall, library, museum, portrait gallery and laboratory.

Death at One Hundred and One Years.—Mrs. Richard B. Cummings of this city, who died last week at the age of 101 years, is survived by six children, of whom the oldest is a son of seventy years; twenty-three grandchildren, and three great-grandchildren.

Antivivisection in Europe.—Even Paris has become infected with the antivivisection movement and on March 5 a largely attended public meeting was held under the direction of the International Antivivisection Union to protest against alleged brutalities of vivisection, and to demand restrictive legislation. The speakers included prominent members of antivivisection organizations in France, England, Germany, Holland and Belgium.

Dr. Jacobi's Address on Nihilism and Drugs.—Our attention has been called to a very evident error in the report of this address in our issue of February 1, page 199. It is there stated that one-half grain of atropine may be given to a child in enuresis without producing symptoms of poisoning; this should have read, one-half grain of extract of belladonna.

A New Laryngological Journal.—A new bimonthly devoted to laryngology and allied provinces is to appear with the title of *Zeitschrift für Laryngologie, Rhinologie, und ihre Grenzgebiete*, under the editorship of Dr. Felix Blumenfeld, Taunusstrasse, 4, Wiesbaden, Germany. The list of collaborators is very large and comprises the names of many of the most prominent workers in these specialties.

Association of American Medical Colleges.—The next annual meeting of this association will be held at the Hotel Euclid, Cleveland, Ohio, March 16 and 17, 1908. All those interested in medical education are cordially invited to attend and participate in the discussions. It is desired that the attendance include not only medical educators, but educators in general, members of State medical examining boards, and representatives of allied associations which discuss educational problems. The *President* of the association is Professor H. B. Ward, Lincoln, Neb., and the *Secretary-Treasurer*, Dr. Fred C. Zapffe, 1764 Lexington street, Chicago.

Long Island Society of Anesthetists.—At its spring meeting this society will consider the subject of modern European methods of anesthesia. The principal paper will be read by Dr. Mary Rupert of Philadelphia. The profession generally is cordially invited to attend.

St. John's Hospital, Long Island City.—The new wing of this hospital, erected at a cost of $250,000, was dedicated by Vicar-General McNamara on March 6 in the presence of many spectators. The building measures 60 by 125 feet, is six stories in height and is to accommodate 200 patients.

Medical Society of the Missouri Valley.—The coming meeting of this society will be held in Lincoln, Neb., March 19 and 20, at the invitation of the Lancaster County Medical Society. Dr. W. F. Milroy of Omaha is president of the society and the secretary is Dr. Chas. Wood Fassett of St. Joseph, Mo.

Queen's University.—On January 14 the new medical laboratories building of Queen's University, Kingston, Ont., was formally opened. The laboratories are for the departments of biology, histology, pathology, physiology, and bacteriology.

Dr. William H. Taylor was tendered a dinner at the Queen City Club, Cincinnati, on the evening of March 2 in honor of the fiftieth anniversary of his graduation in medicine. Later in the evening he addressed the Academy of Medicine on "Fifty Years' Practice of Medicine in Cincinnati." At Dr. Taylor's right and left at the dinner table were Drs. Byron Stanton and B. P. Good, with whom Dr. Taylor had practised for fifty years in Cincinnati.

St. Louis Medical Society.—A Section on Urology of this society was organized on February 18, with the following officers: *Chairman*, Bransford Louis; *Vice-Chairman*, E. A. Scharff; *Secretary-Treasurer*, H. N. Lyons; *Editor*, O. L. Suggett.

Obituary Notes.—Dr. Oliver John Davis Hughes of New Rochelle died suddenly in his office on March 5 at the age of fifty-three years. He was born in Buenos Ayres, received his preliminary education in England, and was graduated from the Long Island College Hospital in 1875. Dr. Hughes was an assistant surgeon in the Franco-Prussian War, then became a surgeon in the United States Marine Corps, and with the rank of lieutenant-colonel was sent by this Government on special service to Vera Cruz, City of Mexico, Japan and Cuba. After his return from this tour he accepted the post of consul-general at Coburg, which he held from 1897 to 1904. He was the recipient of many foreign decorations and other distinctions.

Dr. Richard Douglas of Nashville, Tenn., died on February 21 at the age of forty-eight years. He was graduated from Jefferson Medical College in 1882 and had held numerous teaching and official positions, including the professorship of gynecology and abdominal surgery in Vanderbilt University, the presidency of the Southern Surgical and Gynecological Society, and the presidency of the Nashville Academy of Medicine. He was the author of a volume on abdominal surgery entitled Surgical Diseases of the Abdomen.

Obituary.

DANIEL BENNETT ST. JOHN ROOSA, M.D., LL.D.

NEW YORK.

Dr. D. B. St. John Roosa died suddenly at his home in this city on March 6 in the seventieth year of his age. Dr. Roosa was born in Bethel, N. Y., of colonial ancestry, all his great-grandfathers having been officers in the Continental army. He received his early education in Bethel and at academies in Monticello, N. Y., and Honesdale, Pa., entering Yale University in 1856. Ill health compelled him soon to leave the university, and after studying for a time with a private tutor he began his medical studies in 1857 in the Medical College of the University of New York, from which he was graduated in 1860. He served as interne in New York Hospital and then enlisted as assistant surgeon to the Fifth New York Volunteers, later also serving as surgeon of the Twelfth Regiment, N. G. S. N. Y. At the close of the war he began practice in this city. Until 1882 he was professor of diseases of the eye and ear in the University of the City of New York, and from 1875 to 1880 held a similar chair in the University of Vermont. It was largely as the result of his initiative that the New York Post-graduate Medical School and Hospital was founded twenty-six years ago, and he was the institution's first and only president, as well as its professor of diseases of the eye and ear.

Dr. Roosa's teaching and official positions were almost too numerous to mention. He was president of the New York State Medical Society in 1879, of the International Otological Society in 1876, of the American Otological Society, and honorary vice-president of the International Ophthalmological Society in 1894. He was president of the New York Academy of Medicine in 1893-94, and one of the surgeons and founders of the Manhattan Eye and Ear Hospital. He was a member of the Union League and Century Clubs; of the Holland Society, of which he was president from 1896 to 1897, and of the Society of the Sons of the Revolution. He received the honorary degree of M.A. from Yale in 1872, and that of LL.D. from the University of Vermont in 1880.

Dr. Roosa's contributions to medical literature were numerous and highly esteemed, among his best known books being a translation of "Troltsch on the Eye" from the German; in collaboration with Dr. C. E. Hackley and Dr. Charles Stedman Bull, a translation of "Stellwag on the Eye"; "Vest Pocket Medical Lexicon," "Treatise on the Ear," "The Old Hospital and Other Papers," "Clinical Manual of the Diseases of the Eye," and "A Doctor's Suggestions on the Necessity of Wearing Glasses."

In 1904 a largely attended dinner in Dr. Roosa's honor was given in this city by representative medical teachers from all over the country to commemorate the twenty-first anniversary of the Post-graduate Hospital and he was presented with a loving cup as a tribute to his services in the cause of post-graduate instruction. Dr. Roosa was an eminent figure in all phases of medical activity in this city and State and was particularly prominent in securing proper legislation on matters relative to the profession. In his death medical science has lost an exalted representative and the practitioner a sturdy and farseeing champion.

THE EIGHTH HARVEY SOCIETY LECTURE.

The eighth of the present series of lectures given by the Harvey Society was delivered on Saturday, March 7, at the Academy of Medicine. The speaker was Professor Ross G. Harrison, of Yale University, and the topic, "Embryonic Transplantation and the Development of the Nervous System."

The speaker said he would attempt to show how the experimental method helped us in the study of embryological problems. In embryology this had given us a great deal of valuable information. The embryo was a very delicate mechanism, and our methods in comparison were very crude. Furthermore, the embryos of the higher organisms were so well protected in the body, that they were scarcely accessible to study. It had been necessary, therefore, to go to the lower forms. Certain animals, such as the frog and fish, lent themselves readily to experimental study. It had been found, also, that the embryos of these forms were in many ways so closely related to those of man that we could transfer the generalizations from them to man. There were two general methods of studying this subject experimentally. In the first, whole embryos could be subjected to changed environments, *e.g.* as regards temperature, illumination, nutrition, etc. In the second the immediate environment of a developing part was altered, *e.g.* by removal, or transplation. One of the most important discoveries along the second line of procedure was made in 1894 by Born of Breslau. This investigator showed that when pieces of frog embryo were cut apart they could often be made to heal together again. This discovery led him to take parts of different embryos and by causing them to grow together, to produce all kinds of monsters.

The speaker here showed lantern slides to demonstrate what Born and his successors had done. Two tadpoles joined together by their heads; part of one tadpole transplanted into the entire body of another, etc. Born had also shown that it was possible thus to join individuals of different species, *e.g. Rana esculata* and *Bombinator igneus*. Professor Harrison also showed the picture of a frog he had constructed by planting two different kinds of tadpoles together. The different coloring persisted in the fully developed frog and showed where the two had joined. The reason these experiments were successful was because in the frog the wounds tended to heal so readily. There was the further advantage that at the time when the experiment was done there was no circulation, and each cell was quite capable of independent life. At this early period of life, therefore, one could make any kind of physiological impossibility. Later in life this was impossible, for the transplanted tissues had to have certain relations with the environment; the cells could no longer live independently.

By growing the head end of one kind of frog embryo on the tail end of another kind it had been found that it was possible to trace the development of certain cutaneous sense organs. These appeared in the form of a row of dark spots, and developed from the head end. From there they spread over to the transplanted tail end. There was also a shift of skin from the head end to the tail end, though this was not so marked. In certain experiments it was necessary to remove the entire spinal cord from certain frog embryos. In order to keep such embryos alive, the speaker had

simply grafted such an embryo on a normal one. In this way the normal embryo acted as a kind of nurse for the helpless one.

The speaker next described the technique of these transplantation operations. Born's original method was very crude, for he had dealt with larger pieces. It was necessary to remember that the organisms were very small in the embryo stage, about three millimeters in length. Warren Lewis of Baltimore had introduced a refined technique, and this he had been able to do owing to the introduction of the binocular microscope of Zeiss. This afforded an erect image with sufficient magnification, so that one could transplant pieces such as the Gasserian ganglion, or the ear, or the eye. As a result of such experiments it had been found that the crystalline lens of the eye could develop out of any part of embryonic skin, provided that this was brought in contact with the optic cup.

Experiments of this kind, the speaker said, must be made to solve definite problems. He would therefore ask attention to certain problems in the development of the nervous system. Among these might be mentioned the origin of nerve fibers, which was still very obscure. There were also such problems as what the nerve fiber was in terms of the cell theory; and whether the nerve path was laid down from the beginning in the life of the embryo, or whether it was gradually developed. Mere study of the normal embryos had failed to solve these problems. The speaker then exhibited a picture showing the very early nervous system. Where the anterior nerve roots were to be there were bundles of spindle-shaped cells, and these were regarded by one school of embryologists as being the parent of the nerve fibers. Next was shown a picture illustrating the interpretation of the school of His. There were large cells in the cord sending out long processes into the region of the anterior nerve roots. Professor Harrison also showed a preparation made by Ramón y Cajal which showed conditions apparently in accordance with His's interpretation. None of the pictures, however, sufficed absolutely to decide the question. The speaker had felt that if he could eliminate each of these two elements in turn, the spindle cells and the large ganglion cells, he would be able to decide their respective rôles. The spindle cells originated in the neural crest (ganglionic crest), and this was accordingly removed in the embryo of *Rana esculata*. In order to prevent any possible regeneration, two such embryos were united back to back. This pair of embryos could swim fairly well; hence the motor nerves were evidently intact. Section showed that this was true. Careful study showed that the nerves were complete except for their sensory fibers and for the covering of spindle-shaped cells. The spindle cells were therefore unnecessary for the development of the nerve fiber from the anterior horn.

Study of the posterior nerve roots was more difficult. Cutting off the neural crest was out of the question because this also destroyed the posterior ganglion cells. Study of rare cases of maldevelopment in the embryo of the salamander had, however, shown that the posterior nerves are also developed from prolongations from ganglion cells.

The speaker then took up the question as to whether the nerve paths were present from the outset, or were developed gradually. He discussed Hensen's theory that the fibers developed from protoplasmic bridges. All cells were connected by such bridges; those that functionated persisted, while the others died out. The theory was very attractive and had been adopted by many physiologists and embryologists. According to the other doctrine, the fibers were merely outgrowths from the ganglion cells, and there was nothing to mark out the path of the nerve fiber. Professor Harrison had sought to study the question experimentally. It could be seen the two theories differed mainly in the importance they attached to the ganglion cells. The speaker said that he had been able to demonstrate that there were no protoplasmic bridges in the development of the funicular fibers of the cord. These grew down from the medulla even though the entire spinal cord had been removed. The fibers then grew down into the mass of loose connective tissue developing after the removal of the cord. When, on the other hand, the ganglion cells were removed, no fibers were developed. It had been shown, however, that a forelimb could be transplanted into the lumbosacral region of another embryo. After a time it would be found that all the proper nerves had developed, but from the lumbosacral cord instead of from the brachial plexus. This had been put forward as an argument for the theory of protoplasmic bridges. The same author had transplanted nerveless limbs, *i.e.* limbs from embryos whose ganglions had been destroyed, and claimed that no nerves developed on transplantation. The speaker said he had repeated the experiments and had had no trouble in getting the nerves to develop under these circumstances. Summing up all the evidence he believed that in the growth of the nerves there were two factors: the energy of growth present in the ganglion cell, and the guiding stimuli in the peripheral tissues.

So far as the relation of his work to the neuron doctrine was concerned, the speaker said that the embryological basis of this doctrine was more firmly established than ever before. He did not wish to go further than this.

The next lecture of this series will be held on Saturday, April 18. The speaker will be Professor A. E. Taylor of the University of California, and the subject "The Rôle of Reversed Ferment Reactions in Metabolism." Professor Schäfer's lecture has been postponed to May 9 from April 11, the date previously announced.

Correspondence.

A SUCCESSFUL MEDICAL PAPER AND ITS PROPER DISCUSSION

To the Editor of The Medical Record:

Sir:—The paper of Dr. Kerr before the Medical Society of the County of Kings on "The Construction of a Successful Medical Paper and Its Proper Discussion" raises the question, Are our medical societies so organized as to secure successful medical papers and their proper discussion? It is a matter of common knowledge that comparatively few medical men attend the sessions of the societies to which they belong, many alleging that they prefer to read the paper rather than to listen to the reading by its author. This want of interest in the papers and discussions of our societies is largely due to the mode of procedure. The papers have had no supervision or revision and usually contain a large amount of ancient history, statistics, or irrelevant matter; the reading is of the most monotonous kind; and the discussion consists of random remarks by members, on the floor, who have given the subject no previous thought. The result has been comparatively small attendance, uninterested audiences, and little or no useful information communicated. In the early history of the Academy of Medicine the attendance became so limited that there was some apprehension that it might fail of realizing the object of its founders, viz.,

to create a scientific medical organization, like the Academy of Medicine of Paris, which would attract the entire profession by the high order of its papers and discussions. The method of attracting members to its sessions finally adopted was the announcement on each card that "a collation will be served *after* adjournment." This appeal to the social instincts of the members had the desired effect and greatly increased the attendance, but it is doubtful if it increased the interest of members in the scientific part of the session.

That the members of the Academy can be attracted to its scientific sessions by a higher motive than its collation offers was demonstrated many years ago. At the period to which I refer a current topic of discussion in the profession was, *Can puerperal fever occur without a lesion?* The leading disputants were Professor Fordyce Barker, in the affirmative, and Prof. Alonzo Clark, in the negative. Being the editor of a medical periodical at that time, and desirous of securing interesting material for publication, I requested the president of the Academy, Dr. James Anderson, to allow me to organize a discussion of that subject. He consented, Professors Barker and Clark promised to open the discussion, and I readily secured other speakers in the affirmative and negative and arranged the order of speaking alternately. For the first time in the history of the Academy the house was crowded and the most intense interest was manifested throughout the entire session. A second session was held to complete the program and at this meeting members attended early in order to secure seats. The discussion was published in full and was largely republished in foreign journals, where the same question was under review, with many complimentary remarks on the success of the New York Academy of Medicine in organizing a discussion of such scientific value. At Dr. Anderson's request I arranged another discussion on a question relating to "Bright's disease," then one of the most current topics of medical interest, and with the same result of crowded meetings during three sessions.

These incidents are very suggestive of the possibility of so organizing the Academy's program as to secure for every session a "successful medical paper and a proper discussion," which will attract a large attendance of the profession. The Academy has, indeed, only to utilize its present organization for that purpose to make it a model in the production of papers and discussions of world-wide value and interest. To this end I submit the following suggestions:

1. Refer all papers to their respective sections for critical examination; the section should report on each paper so referred, whether its subject matter requires that the paper should be read in detail or be formulated as a question—affirmative and negative—for a formal discussion.

2. No business should be transacted at the scientific sessions, but it should be provided for at meetings called by the president. The scientific sessions should have no quorum, and should be conducted strictly according to the order on a postal card issued to each member. The card should state the exact time of reading a paper and of each speaker in a discussion, in order that members may know when to attend to hear the paper or any part of the discussion.

3. The section reporting a subject for discussion should organize it on the basis of a question and should arrange the disputants so that they speak alternately in the affirmative and negative. Each speaker should address the audience from the platform and he should not exceed the time fixed on the card except by unanimous consent. A vote on the result of the discussion should be taken when ordered by a majority of the members present. The chairman of the section which organized the discussion should preside during the session.

The advantages of this scheme of organizing and conducting the scientific sessions of the Academy would soon become apparent. The sections would assume the duties for which they were originally created, viz., as committees they would examine critically all papers presented to the Academy and select those that should be read in full for the information and instruction which they contain, and those that contain only a debatable subject that may be formulated as a question for discussion, affirmatively and negatively. Subjected to such an examination, few papers would be read in detail in the Academy, the subject matter of the larger number being much more intelligently presented in the form of a well-arranged discussion. To the younger members of the profession the Academy would be a school where they would learn and practice the art of public discussion. The senior members of the Academy—practitioners, teachers, scientists—would here meet in friendly rivalry, and with the convincing force of the living voice, gesture, and personality enforce their arguments upon a receptive audience. But the greatest advantage of the change would come to the Academy which would become the recognized forum where the great and vital questions in the medical sciences, which are constantly agitating the profession, are logically discussed and judicially determined.

STEPHEN SMITH, M.D.
300 CENTRAL PARK WEST.

CORRECTION OF UTERINE DISPLACEMENTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the very able treatment of the subject of uterine displacements, by Dr. Frank H. Hancock, in the MEDICAL RECORD for March 7, I find a statement which needs some shortening of its ligaments. "Dr. Morris of New York, finding a retrodisplacement without complications, sends the patient to an eye specialist, and if refractive errors are found has them corrected *and dismisses the patient*" (Italics mine). "O that mine enemy might write a book!" Dr. Hancock has written, and it occurs to me that perhaps others who seem to be inimical to some of my ideas might write in the same way. The patient is dismissed provided that her uterus remains in place after the leak of energy from eyestrain has been calked. This same patient may be sent to a neurologist, to a dentist, to a laryngologist, to a physical culture institute, or to my hospital service for operation. She will not be dismissed until I can satisfy my own curiosity about the cause for her condition, and she will not be operated upon until I have exhausted rational lines for observation.

Many years ago I was taught by masters of approved methods of tinkering, in cases of uncomplicated uterine flexions and versions. After awhile I added an "h" to tinkering, and found myself able to stand aloft upon the uterus, and to wave my arms in freedom. Previously my case had been a confinement case. If there was any specialist who needed to have the long forceps applied to himself twenty-five years ago it was the gynecologist of that day. Very many flexions and versions of the uterus are symptomatic. An anteflexion in the spring may be a retroflexion in the fall. A retroversion following some great grief may correct itself without the help of the doctor. A retroversion following a fall may frequently enough be corrected by the knee-chest position and the vaginal air cushion. There are flexions and versions which seem to be uncomplicated but which require some very nice surgical work. That is why the practice of the profession is superior to the practice of an idea. Dr. Hancock, and no doubt many others, would have me practice an idea.

ROBERT T. MORRIS, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OUT-PATIENTS—HOSPITAL FOR INSANE—VITAL STATISTICS—EMPYEMA—EXCISION OF THE SCAPULA—AURAL GROWTHS—MILK SUPPLY—DANGER OF X-RAYS—THE "TIMES" ON QUACKERY—OBITUARY.

LONDON, February 21, 1908.

YESTERDAY the important announcement was made that the Prince of Wales, on the suggestion of the Committee of King Edward's Hospital Fund, has decided to appoint a committee to inquire into the system prevailing in the London voluntary hospitals with regard to the admission of out-patients. But in view of the fact that some portion of the subject of inquiry would probably fall within the subjects to be reported upon by the Royal Commission on the Poor Laws, the committee will not be appointed until that commission has reported.

Dr. Hy. Maudsley has this week addressed a letter to the London County Council in which he offers to contribute £30,000 toward the cost of establishing a hospital for mental diseases, if the Council will carry out his scheme. The main object, he says, would be (1) the early treatment of cases of acute mental disorder, with the view, so far as possible, to prevent the necessity of sending them to the county asylums; (2) to promote exact scientific research into the causes and pathology of insanity, with the hope that much may yet be done for its prevention and successful treatment; and (3) to serve as an educational institution in which medical students might obtain good clinical instruction. No one perhaps could know better than Dr. Maudsley what is the real need for such an institution, and he enters somewhat more fully in his letter on the points above stated. It appears that the distinguished alienist had mentioned

the scheme to the chairman of the Board last December and no doubt he had long before then cogitated it, for at that interview he had suggested that the hospital should be for 100 patients suffering from recent and mostly acute insanity; that some 60 or 75 should be of the poor class, for whom their parishes would pay, as is now the case with those sent to county asylums. The remainder would pay a sum sufficient to prevent them being any cost to the ratepayers. Dr. Maudsley believes such a hospital, in vital touch with the hospitals and University of London, would do much to break down the isolation from general medical knowledge and research in which he thinks the study and treatment of insanity remains and in the end might save to the rates some of the prolonged expense of chronic and incurable insanity. The thanks of the Council were voted to Dr. Maudsley for his munificent offer, which was referred to the Asylums Committee for their consideration and report.

The Registrar-General's return for the last quarter of 1907 has just appeared and shows that the births registered in that period (in England and Wales) equaled a rate of 24.8 per 1,000 of the population. This is 2.5 below the average, and far the lowest fourth quarter rate on record. The death rate was 14.7 per 1,000. This is 1.7 lower than the average, and, like the birth rate, the lowest fourth quarter rate. The infantile mortality was 136 against an average of 142.

In this quarterly return a brief summary is given of the results for the whole year, which, with the exception of the birth rate, seem satisfactory. This rate was only 26.3, being 2.1 below the average, and the lowest recorded. The death rate was 15.0, being 1.7 below normal, and also the lowest recorded. Infantile mortality fell to 118 per 1,000 births, being 14 below that of 1906, and 27 below the ten years' average, and also the lowest ever registered. The natural increase of population, due to excess of births over deaths, was only 393,315, as against 409,456, the average of the quinquennium preceding. The check to the increase thus amounts to more than 16,000, assuming the population to have been stationary. These facts may be compared with those contained in the Annual Report for the year (1906) last completed, which has also appeared within the last few days, and furnishes many facts which may be compared with the later statements for the briefer period. Some modifications were introduced in these reports with the new century, but not such as to render comparison with earlier ones impossible. There is still a tendency toward expansion of the data provided in these monumental volumes of vital statistics. This is particularly noticeable in the international data, which now include facts as to general mortality and the fatality of epidemics, cancer, and tuberculosis. Infantile mortality in the colonies and abroad also deserves attention in comparison with that at home. It has often been stated that while our adult mortality has long been falling, that of the infantile age has remained unchanged. But this is no longer the case, for the Registrar-General is able to state that since the beginning of the new century there has been a decrease amounting to 11 per cent. of the rate in the previous decennium. The act passed in the last session of Parliament on the notification of births may perhaps be as successful as its promoters hope in further diminishing infantile mortality. A warning note, however, is sounded as to the possible fallacy for a too hasty deduction from recent statistics, inasmuch as we have been enjoying a series of cool and moist summers; such weather, in fact, as is believed to check the rise in infant mortality, which usually takes place in the third quarter of the year. Another subject illustrated in this report is the fall in the birth rate, which has steadily progressed of late years until it amounted to 20 per cent. on the total number of women at child-bearing ages. Reckoning on the rates of births to wives of such ages, the decrease has reached 25 per cent. The legitimate births in 1906 were less by 30,000 than they would have been had the ratio of 1876-80 been maintained. It seems obvious, as Sir W. Dunbar remarks, that much of the decrease is due to deliberate restriction of child-bearing.

Mr. A. E. Morison has committed to the Edinburgh Medical-Chirurgical a careful paper on "Empyema," founded on 100 consecutive cases. After considering the physics of pleural effusions and the diagnosis, he went on to say that the prognosis in empyema is good, his mortality having been only 3 per cent. Natural cure might take place by absorption or by spontaneous evacuation into adjacent organs, or through the chest wall, when the accumulation was large, but subsequent operation might become necessary. Surgical treatment from the first was therefore best, and, in his experience, treated with proper care, empyema was hardly serious. His three deaths were due to bronchitis, marasmus and cerebrospinal meningitis, respectively. The perfect recovery of the others was most satisfactory. Aspiration was only of service when dyspnœa was extreme or some complication contraindicated operation. The site of preference for incision was the sixth interspace, just in front of the posterior axillary line. He made a vertical incision through the skin and a horizontal one through the muscles along the upper border of the seventh rib. Then he introduced sinus forceps and dilated the wound by withdrawing them open. A rubber tube one-quarter inch in diameter and two inches long was passed and prevented from slipping in by a safety pin in the free end. When the discharge became small the tube was cut in half, dressing with sublimate wool. Mr. Morison laid down the following conclusions: (1) Pleuropneumonia is the most frequent cause of empyema; (2) empyema rarely follows pleurisy with effusion; (3) in adults it is more likely to be secondary to serious lung disease than in children; (4) the diagnosis is not always easy; (5) the exploring needle should be used in all doubtful cases and in more than one situation; (6) there is no danger in using the needle with proper care; (7) the immediate prognosis in complicated empyema, treated by incision and drainage, is good; (8) the remote prognosis is excellent, no deformity following and no sequelæ resulting; (9) careful asepsis must be carried out; (10) resection of the rib is needful in some neglected cases, but generally is meddlesome surgery.

At the Clinical Section of the Royal Society of Medicine, on Friday last, Mr. R. P. Rowlands showed a man of thirty-five, from whom the whole of the body of the left scapula was excised fifteen months ago for enchondroma. He was able to save the coracoid process, with its muscles and ligaments, the glenoid cavity with the capsular ligament and the acromion process, with the attachments of the deltoid and trapezius. Both the functions and the deformity in this case were evidently less than after complete excision of the scapula. The man had been able to work as a painter's laborer from two months after the operation. It was thought that preservation of the processes of the glenoid cavity was practicable and preferable to complete excision for inflammatory conditions and for benign growths, possibly also for some malignant growths.

There were some very interesting cases in the Otological Section. Let me cite a couple. Mr. Whitehead read notes of one which started with aural polypus, recurring on removal. The mastoid operation was done when the growth was found to extend deeply into the cochlea and petrous portion and forward, involving the Eustachian orifice. Hemorrhage, profuse but arrested at length by pressure. Eight weeks afterward the cavity was dry and covered with epithelium. No recurrence since (twelve months). The growth appeared to be atypical carcinoma, and was referred to the growths committee for further examination.

Dr. Barry Ball showed a case of pulsating growth in the left external auditory meatus in a man of seventy-three, who consulted Dr. McBride ten years ago. There was then a small growth in the meatus, which has increased steadily with an occasional hemorrhage. It now protrudes, and there is distinct, expansile pulsation in it, which is communicated to the auricle and pre-auricular regions. It seems to be an endothelioma. The question of tying the external carotid was discussed, but the general opinion seemed to be against, considering the patient's age and the duration of the growth.

Our milk supply is the subject of a disquieting report by Dr. Collingwood, Medical Officer of Health for the City. In continuation of previous inquiries, twenty-four samples were taken in November on arrival from three districts, and submitted to Dr. Klein. Of these, thirteen were fairly clean, two tuberculous, and nine dirty. Thus 8.3 per cent. were capable of producing tuberculosis, and of the remainder 37.5 per cent. were dirty. Dr. Collingwood remarks that although the unclean percentage on this occasion is higher, the tuberculous percentage shows slight variation from that in previous examinations. Traced to their origin, one of the tuberculous samples was from a farm in which the premises were in a satisfactory condition, but one of the cows, on inspection, was found to be tuberculous, and slaughtered. The other was from a herd in which three were suspected, found to react, and removed. It appears that no precautions are taken by the farmers at the source, nor by the dealers on arrival in London, and yet, as this report shows, there is no difficulty in dealing with the milk

at the source by the local authorities. The central authority need not waste time or money on inspecting farms. Dr. Collingridge's work shows that it is only necessary for each local authority to determine the condition of the milk, and, when satisfactory, furnish a report to the board of the district and also to the Board of Agriculture—the latter to take action if the former neglects to do so. The dirty state of samples is due to such causes as unlocked and unsealed churns and the system of mixing at the railway stations adopted by dealers. It is said, too, that the churns are often returned unsealed and unwashed to the country, where the farmers, in their turn, neglect to purify them. These are certainly duties which should be rigidly enforced on great companies as well as on the smaller dealers. The subject was before the House of Commons last night, when Mr. Burns stated he hoped to bring in a bill shortly to control the milk supply, and he also gave information about a recent increase in the importation of milk, cream, etc., from abroad.

Dr. Hall Edwards, of Birmingham, has lost an arm under circumstances calling for deep sympathy. He was an early worker with *x*-rays, and went to South Africa as a specialist with the Imperial Yeomanry. He has since been continuing the work, and has suffered much from the effects of the rays on his left hand. As the arm was becoming affected, it has been amputated.

On Saturday, the *Times* had a leader chiding "certain publications" for the unwarrantable statements of quacks in their "advertisement sheets." Saul, among the prophets, sneer some, as they point to the advertisement sheet of the *Times*, where quackery daily makes promises impossible of fulfillment and "false to the knowledge of those who make them."

Dr. Fancourt Barnes died yesterday, aged fifty-nine. He graduated at Aberdeen, M.B., 1875, M.D., 1878. He served as Physician to the Royal Maternity Charity and British Lying-in Hospital, Obstetric Physician to the Great Northern Central Hospital, and other institutions. He was editor of the *Gynecological Journal*, and at one time sub-editor of the *British Medical Journal*. He wrote numerous articles on obstetrics and gynecology for journals and papers for the societies. In 1893 he recorded fifty consecutive abdominal sections. He was the translator of Martin's "Atlas of Obstetrics and Gynecology," and joint author with Robert Barnes of the "System of Obstetric Medicine and Surgery." He also published a German-English Medical Dictionary. He was a corresponding member of several societies devoted to his specialty, including that of Boston, U. S. A.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 27, 1908.

Treatment of Trophic Nerve Lesions: A Study Based on a Case of Mal Perforans; of Ischemic Paralysis and Erythromelalgia.—W. C. Quinby advances the following conclusions: (1) That the so-called trophic nerve lesions of the skin, bones, and joints are due to a break in what we have called, for convenience, the neurovascular mechanism of the part involved. (2) That this break may be situated centrally, or on the neural side, or on the vascular side. (3) Hence rational treatment of such conditions will be directed toward modification of (*a*) the blood supply, or (*b*) the nerve function of the part. (4) For modification of the blood supply we have active and passive hyperemia increasing it, and positive pressure by bandaging, pneumatic cabinet, or the immersion in mercury decreasing it. (5) For modification of the nerve function we have nerve stretching, neurolysis, and nerve disassociation and electricity. (6) Nerve stretching is probably to be condemned, similar results being obtainable by the simpler passive hyperemia.

Pulmonary Embolus Following Operative Interference.—C. G. Cumston refers to a doubtful case of pulmonary embolus following an exploratory laparotomy which revealed papillary ovarian cysts. No autopsy was held and diagnosis was not positive. More recently, however, he has operated on a young woman for ovarian cyst in which an autopsy revealed pulmonary embolism. The attack came on without a moment's warning, although there were certain favorable conditions in the case for thrombus formation. Death came on the twentieth day after operation, the patient having been sitting up daily for over a week. The writer goes on to discuss the question of pulmonary thrombus, setting forth the various theories extant. Various causative factors are slowing of the circulation, changes in the density of the blood as well as in its anatomic elements, cardiac lesions, increased resistance in the peripheral circulation, which occurs in pregnancy and pelvic neoplasms, etc. In many cases it is impossible definitely to determine the cause. In mild cases the breaking off of the thrombus and the lodgment of the embolus are attended only by slight dyspnea and possibly a little vertigo and the patient recovers. The other extreme is the type in which the patient develops intense dyspnea, grows cyanotic and unconscious and dies in a very few minutes. We know of nothing to prevent the accident and can really do nothing for it.

New York Medical Journal, February 29, 1908.

The After-Care of the Insane.—F. Petersen reminds us that the circumstances surrounding the insane differ from those associated with other forms of illness. Insanity is a protracted malady and convalescence and cure are matters of months or even years after admission to hospitals. When the poor and friendless insane are finally discharged, they come almost as strangers into the community and are often wrongly regarded, if their history is known, with some degree of suspicion or even apprehension. These conditions have a bad effect upon the patient himself and tend to cause a recurrence of his malady. The author briefly reviews the efforts which have been made for establishing in this country after-care societies for this class of patients and heartily advocates its further extension. The rather unusual needs of the insane as compared with the needs of other convalescents, has led of late to some extension of the functions of an after-care society, so that the qualification "after-care" does not fully represent the present conception of such an organization. An organization of the kind desired is one made up of hospital physicians, local practitioners, lawyers, clergymen, business men, and their wives, and as they become familiar with all matters pertaining to the insane through their relation to the immediate objects of after-care, will diffuse ideas of prophylaxis through the community and educate the people in this important department of public health. Not only will preventable causes thus be more generally recognized and more strongly combated, but the public will become more alive to the need of early treatment and take advantage of the opportunities now afforded for medical advice in mental disorders at outdoor departments of city clinics and country asylums.

The Gastrointestinal Symptoms of Middle Ear Suppuration.—L. Fischer says that in examining cases of gastrointestinal disease, one should never overlook the possibility of there being the initial stage of scarlet fever or middle-ear trouble. He notes that the ear may easily become infected through the Eustachian tube by material which in the act of vomiting becomes lodged in the nasopharynx. The gastrointestinal symptoms due to the toxemia from a pneumococcus or streptococcus infection of the middle-ear through the nose and nasopharynx appear as follows: In the breast-fed case, the child becomes ill suddenly, has vomiting, diarrhea, greenish stools, fever, rapid pulse and breathing, hot skin, erythematous or urticarial rashes, apathy, meteorism, flatness and flatulence, congested throat and acetone odor on the breath. The glands are not involved. In the bottle-fed case the symptoms are of the same general variety but of a more severe type. They may be ushered in by convulsions. Evidences of a true enterocolitis quickly appear. Indican is present in the urine, evidencing a disturbance of metabolism due to putrefactive absorption. When intestinal digestion is impaired in spite of eliminative treatment and careful dieting it proves that the seat of the trouble is located elsewhere. Blood-counts may suggest suppuration, especially if the polynuclear percentage is very high. In a normal infant during the act of crying or screaming the drum membrane appears pink or rose colored. It is advisable, therefore, to examine the ear gently and quickly while the infant is asleep to prevent its waking and crying.

The Present Status of the Etiology of Syphilis.—R. C. Rosenberger reviews the literature of the *Spirochæta pallida* with relation to its biology and etiology. Nothing new is presented but the paper is a valuable summary and represents an exhaustive search through recent publications. The various subheadings are morphology, occurrence in specific lesions, and cultivation experiments. The author's observations have convinced him that *S. pallida* is the probable cause of syphilis. In congenital cases though it has been found most constantly, it is not always generally distributed in all the organs and tissues. It may be in only one or two organs, the liver and spleen, kidney or skin, and then only in certain areas of any of these structures. The author says that anyone who has had histological training should not mistake the parasite when stained by the Levaditi method, for any tissue fibers in the different organs, while in spreads from lesions or organs it most certainly takes a practised eye to distin-

guish between delicate shreds of tissue and spirocheta, especially when stained by the anilin dyes or any of the stains for blood. Another point must also be borne in mind, and this is the certain disappearance or diminution in the number of parasites, when local or general treatment is resorted to. The examination should be made as early as possible, and Rosenberger believes that the best stains to use for spreads from lesions or organs are Giemsa's azure eosin and the blood stain of either Wright or Leishman.

Orthopedic Therapy During the Early Stages of Acute Anterior Poliomyelitis.—J. J. Nutt reminds us that the disabilities in this disease are due to the paralysis and the deformities. The latter result from unopposed muscular action, from asymmetry in development, and from weight bearing in an abnormal position while the sustaining tissues have their motor and trophic centers paralyzed. The treatment, therefore, before the chronic stage, should be directed toward: (1) Keeping the parts in as healthy a condition as possible; (2) the preservation of the normal range of motion in all the joints; and (3) preventing stretching and elongation of paralyzed and weakened tissues. For the relief of (1) we may use massage, electricity, heat, and hydrotherapy. For (2) passive movements should be carried out daily from the beginning of the treatment. Muscle shortening begins within a very few weeks. Normal movements may be impossible without the use of force as early as six weeks after the outset of the disease. For (3) we have various muscle-relaxing apparatus. Care must be taken not to overstretch the muscle. Illustrative clinical histories are given. Prolonged rest in bed does not appeal to the author as the wisest course to follow.

Journal of the American Medical Association, February 29, 1908.

The Endogenous Uric Acid in Pathological Conditions.—R. E. Peck and F. W. Thompson report a series of experiments undertaken to solve the problems of the variation from normal in the output of urinary uric acid in pathological conditions other than gout, and what is the best method for increasing the output when it is below normal. Thirty-one patients were examined; of these 17 (54.8 per cent.) showed the urinary uric acid to be below 0.250 gram in twenty-four hours, 22 patients showed marked nervous symptoms (melancholy, dizziness, blurrings of vision, pains referred to different parts of the body, etc.), and in 14 of these (63.6 per cent.) the condition was diagnosed as neurasthenia. Of these 14, only 4 showed the urinary uric acid over 0.250 gram; 5 patients had rheumatic symptoms, and 2 were normal. In every case a purin-free diet was ordered for at least two days prior to the collection of the first sample and continued throughout the observation. Folin's methods were used for the determination of uric acid and Kjeldahl's method for the total nitrogen. The treatment consisted in the use of drugs, diet, and electric light baths. In two patients, experiments were undertaken to determine the relative effects of hot-air and electric-light baths. The hot-air baths were followed by a remarkable and unexpected drop in the uric acid output, unexplainable by increased perspiration, as it continued on days when no baths were given. The conclusion drawn was that this kind of bath inhibits the formation or increases the destruction of uric acid and might be of use in conditions where abnormally high amounts of this substance were present. The electric-light bath did not have any effect when a normal amount of uric acid was being excreted, but taken when there is an abnormally low output this treatment increases considerably the quantity eliminated, if not always to a normal amount. The results are tabulated and the authors' conclusions stated in substance as follows: 1. A certain proportion of patients showing nervous and other symptoms are suffering from disturbances of metabolism of such a nature as to lead to an abnormally low output of endogenous urinary purins. 2. Just what these metabolic abnormalities are we cannot at present say, because of ignorance of the exact physiological processes concerned in the formation of the endogenous moiety, but that they are, in a measure at least, responsible for some of the symptoms, is shown by the relief of these same symptoms on the increase of the elimination of the urinary purins. 3. The best method of bringing about this result is not by trying to dissolve the uric acid, as has been our endeavor in the past, but to increase the activity of the metabolic processes. This latter end is best attained by exposing the naked body to the direct rays of incandescent electric lights.

The Choice of a Vasodilator.—H. W. Cook calls attention to the advantages of sodium nitrite over nitroglycerin and amyl nitrite as regards stability and permanence and certainty of effect. Its action usually is manifest in from three to five minutes when given by the mouth, and in about two minutes when given hypodermically, and is maintained from one to two and a half hours. Both of the other drugs, while quicker in action, are less reliable and less lasting in their effects. A great recommendation of sodium nitrite is the almost entire absence of general effects when given in proper doses; the throbbing, dizziness, flushing, etc., often so annoying with amyl nitrite and nitroglycerin, are slight or absent, and Cook has never observed the headaches so common with the continued use of nitroglycerin, to follow that of sodium nitrite. He has found it most convenient to give it in triturates of one-half and one grain each. They may be used either by the mouth or hypodermically. He reviews the indications for vasodilatation in conditions of low and high arterial tension, insisting on the necessity for the use of the sphygmomanometer in the treatment of every case of cardiac, renal, or arterial disease. Any attempt, he says, to regulate arterial tension without any knowledge of its degree or action under treatment, is working in the dark. One-half grain of sodium nitrite is a safe initial dose in an untried case, and a three-hour interval between doses. The adjustment of dose and interval must be regulated by the sphygmomanometer. His conclusions are summarized substantially as follows: 1. Sodium nitrite is the best vasodilator; it has the most enduring effects; is most stable and dependable; gives rise to the fewest unpleasant symptoms. 2. Vasodilatation may be indicated with low or normal tension, *i.e.* all uncontrollable hemorrhage, either during operative manipulation, typhoid ulceration, gastric ulcer, pulmonary hemorrhage, other internal hemorrhages uncontrollable by surgical methods, aneurysm or thrombus. 3. High tension is abnormal and either accompanies organic disease or else presages its onset; in either case it demands treatment—first, by general hygienic measures; second, when necessary, by venesection or vasodilatation with drugs—preferably sodium nitrite.

The Operative Treatment of Epilepsy.—M. Woods advocates more frequent resort to surgery for the cure of epilepsy, basing his recommendation on the theory that the disorder is an apyretic paroxysmal neurosis, and that the strong impression made on its neurotic victims by surgical procedures will often have a directly curative effect. He reports from his own case records three instances of apparently lasting arrest of the attacks after surgical operations and traumatisms involving surgery, and refers also to the frequently observed fact of the temporary arrest of the paroxysms after almost any kind of an operation. One of his cases is that of a woman, aged 42, who had been an epileptic for twenty years, who burned her hand on a red-hot grate in an attack, the hand requiring amputation. She continued free from the disease till her death, eight years later. He refers to other similar cures reported by various authors, and holds that, altogether, they justify a claim for more frequent resort to surgery in this disease.

Cardiac Arrest as a Cause of Epilepsy.—Following out a suggestion of Dr. A. E. Russell of London that cerebral anemia might be a common condition produced by all the underlying causes of the epileptic seizure, and that arrest of the heart's action may in some cases be the immediate cause of the anemia, for which he produced some evidence, J. F. Munson undertook to secure a series of graphic records of the pulse of epileptics just prior to their attacks. The difficulties of this, taking into consideration the fact that the exact time of no seizure could be foretold, are obvious, but he succeeded in obtaining records in ten cases, which are reported, by means of an air transmission whereby the pulsations in a constricted limb were recorded on blackened paper on a drum for a period of many hours, the patient lying in bed or bolstered up by pillows in a convenient position. While there was no time-recording apparatus attached, he is satisfied, from several months' experience with the kymograph, that its motion was sufficiently regular for the purpose of his study. The patients were taken at random, except two or three selected on account of heart lesions. They can, he says, be accepted as representing the average of epileptics. In only one case was there a very slight slowing observed, in all the others there was an acceleration of the pulse preceding the attack and lasting through the onset stage to the moment of the first recorded convulsion. The acceleration was never great, from eight to nine, or from twelve to fifteen or seventeen beats. In all cases the pulse was entirely regular. For this group of cases, Munson says, one can conclude definitely: 1. Cardiac arrest does not occur. 2. Except for slight acceleration, and in one case slight slowing, the heart does not take part in the convulsion. While there is no doubt as to the accuracy of these conclusions for the cases observed, he does not pretend to say that they apply to all epilepsies. It is doubtful, he thinks,

however, whether cardiac arrest will be found in cortical epilepsies uncomplicated by heart lesions.

Uninfected vs. Disinfected Hands.—According to J. H. Carstens, the only remaining practical problem in aseptic surgery is that of how to make the hands sterile. While this has been accomplished to a considerable extent, we still get cultures from so-called sterilized hands and the only way in which we can obtain an approximately good result is by never getting hands or fingers where there is liable to be infectious material. We can probably never accomplish this perfectly, but we can do a good deal if we try. His technique is given as follows: If he has to operate for an ordinary ovarian tumor or a fibroid tumor, or do an "interval" appendectomy or a gallstone operation, he operates with bare hands. If on opening the abdomen he finds suddenly something he did not expect—a quiescent pus tube, complicating the ovarian or fibroid tumor, or if he finds that the appendix has ruptured and is walled in and lying in a puddle of pus; or if he finds he is dealing with tuberculous peritonitis or a malignant growth—he stops at once, turns around to a basin containing gloves and puts them on, which takes about a minute. He then proceeds with the operation with the gloved hand. In case of previously diagnosticated infection, or in intestinal surgery, or whenever there is any doubt, he uses gloves from the first. If we always use rubber gloves we come to depend on them too much. Gloves tear and puncture during operations, especially if they are thin, and if thick they interfere with rapid work. If they tear, the infection of the hand is carried to the patient, or the patient's infection contaminates the hand. Carstens doubts also whether gloves can be always sterilized by boiling for a few minutes in water; certainly many spores are hard to kill. In his work, aside from operations, he follows the same rule, never examining an infected or puerperal uterus with the bare finger, but always with gloves. He never makes a vaginal, rectal, or any other kind of examination, never dresses a patient in whom there may be an abscess or fistula, or a case that requires drainage, without using rubber gloves. In this way he thinks he can keep his hands clean by absolute avoidance of infection. With this and the rapid work permitted by the ungloved hand, it seems to him that a surgeon can increase his success and reduce his death rate.

The Lancet, February 22, 1908.

Night Blindness.—J. H. Parsons reviews the principal features of retinitis pigmentosa. Routine examination shows that there is little disturbance of central vision. A view of the fundus in early stages in young patients shows a zone of retinal pigmentation in the neighborhood of the equator, spots shaped like bone corpuscles and aggregated along the perivascular sheaths of the retinal vessels. A ring scotoma, seldom complete, is also visible at this time. At a later stage the zone of pigmentation has extended both peripherally and centrally, and the field now shows uniform contraction, the peripheral area of vision having become abolished. The progress is usually very slow and central vision is seldom lost by the extension of the choroido-retinal disease to the macular area. Before this occurs a posterior cortical opacity appears in the lens, which, however, has much the same effect upon the visual acuity. This so-called idiopathic retinitis pigmentosa is a progressive form of chronic night blindness. It is an obscure disease in which heredity and the consanguinity of parents plays a considerable part. In reality the choriocapillaris of the choroid seems to be first attacked, the retinal degeneration being secondary. The outer layers of the retina are nourished by the choriocapillaris and in retinitis pigmentosa the inner layers show comparatively little change. These facts help us to a reasonable conjecture as to the exact causation of the night blindness. There is a chronic hereditary form of the disease which is stationary and shows no changes in the fundus. There are also acute cases. Syphilitic pigmentary retinitis represents in some respects an intermediary form between chronic night blindness and idiopathic retinitis pigmentosa. Malnutrition is an important factor in these intermediary cases. Still another form is that associated with jaundice in severe cases of which this visual disturbance is not uncommon. In some instances pigmentary changes of slight degree have been found in the retina and the condition has been dignified with the name ophthalmia hepatica; in most the ophthalmoscopic signs are negative. It is noteworthy in this connection to recall the fact that bile salts are a solvent of the visual purple, as was shown by Kühne. Night blindness is common in India among badly-nourished natives, especially during the periodic famines. It has been found that the symptom disappears when the patients are fed on liver, a fact difficult to correlate with the cases occurring with jaundice.

Pneumococcic Suppuration in Femoral Aneurysm.—H. H. Clutton and L. S. Dudgeon report a case of aneurysm of the femoral artery in a man of 78 years in which suppuration occurred from pneumococcic infection. He passed through a pneumonia of the influenza type and about a month later began to have a swelling in the course of the femoral vessels on the left side. In the course of a few weeks the swelling began to pulsate and finally presented all the signs of an aneurysm in Hunter's canal of the left side, with inflammatory exudation into the tissues around. It was decided that the mass was a sacculated aneurysm on the outer side of the femoral artery in Hunter's canal. Four months after the onset of the pneumonia, when the entire mass reached the apex of Scarpa's triangle and occupied the middle of the thigh, the femoral artery was ligated just above the swelling. The patient recovered well from the operation, but the mass continued to increase in size and gradually assumed the physical characteristics of an abscess. It was continuously incised and what was evidently old softened clot escaped in large amount, but no direct arterial communication with the cavity could be made out. Counter openings were made and the whole area thoroughly drained. The man made a good recovery. Examination of the clotted material which escaped showed pure cultures of the pneumococcus. There was no positive evidence to show the existence of an aneurysm before the pneumonia attack.

Three Cases of Poisoning by Carbonic Oxide; One Recovery.—The cases are reported by R. S. Pearson. The patients, women, retired for the night in a room heated by a stove and were found unconscious the next morning. Two of them, aged respectively 47 and 52 years, were dead. The third, aged 76, was alive and was saved, artificial respiration having been begun at once and continued for a long time. Her pupils were equal and of moderate size; she was practically pulseless and was breathing stertorously, the cheeks blowing with each expiration. Respiration was slow (about 12 to the minute), the lips and mucous membranes were bright, and the complexion was clear. Both wrists showed abrasions the result of the continued efforts at artificial respiration, and it was noted that the reddened skin around the wrists had a peculiarly bright hue. As there was no information to go upon, and as there was a suspicion that all three had partaken of the contents of a mysterious parcel left by a visitor, after injecting one-sixtieth of a grain of strychnine it was decided to wash out the stomach. This was done with warm water and afterwards with weak Condy's fluid till the washing was clear; the washings were first of a coffee-ground color. One and a half ounces of brandy were then given through the stomach-tube, and after injection of ether and the application of the interrupted current in the course of the phrenic nerve, after about three hours the pulse improved, the conjunctival reflex returned, and she responded to outside stimuli. Oxygen was sent for, but she recovered before it arrived. A specimen of blood submitted to the spectroscope revealed the absorption bands of CO hemoglobin.

British Medical Journal, February 22, 1908.

On the Incidence and Spread of Cancer.—G. L. Cheatle has collected 58 cases in which cancer began in the skin of the hand. All but one (a rodent ulcer) were squamous epithelioma. In all but two the growth began on the back of the hand. The points of incidence in these 54 cases are as follows: In 28 of them the disease began either exactly over or to one or the other side of the second metacarpal bone. In 16 of these 28 cases it began on the radial side of this bone. In 22 of the 54 cases the disease began about the middle of the shafts of the third and fourth metacarpal bones. In 4 out of the 54 cases the disease beban on the ulna side of the fifth metacarpal bone near the wrist. Out of the 56 cases 32 began on the right hand and 24 on the left. In 4 cases there were squamous epitheliomata of both hands (backs); in one of these patients there was in addition a rodent ulcer on the right temple. The majority of the cases are males. The author says that the clinical connection between external irritations and cancer is very noticeable. The incidence of cancer appears to him to be closely associated with those points at which nerves become cutaneous. Besides affecting the epithelium of the skin locally, external irritation also affects the posterior spinal root ganglion supplying that skin and its epithelium, so that changes in the skin which are observed when external irritation is applied to it may be partly, chiefly, or wholly due to impulses received or not received from the posterior spinal root ganglia.

Oral Filter to Be Worn During Operations.—G. E. Duncan gives an illustrated description of the filter, which is a simple one, consisting of a square of cheese cloth measuring 3 feet 1 inch along each border. This square is folded up like an ordinary handkerchief and is steril-

ized with the dressings. After the surgeon, his assistants, and others in the operating room have sterilized their hands and put on their operating coats they apply the muslin filter in this manner: Unfold the muslin from its handkerchief form until one fold remains, that is, the muslin is simply folded once, its area being halved. Grasp the folded edge with both hands and fling the muslin over the head, bring the center of the folded edge down to the center of the forehead just above the eyebrows, pass the folded edges behind both the ears, exposing the free ends down over the shoulders on to the front of the chest. Now strip (on both sides) the anterior free edge from the posterior free edge up to the level of the lobe of the ear. Now bring the posterior free edge across the face at the level of the bridge of the nose. Likewise the remaining posterior free edge across the nose, tucking the end in, about midway between the outer canthus of the eye and the external auditory canal. Now pull up the collar of the sterilized coat round the muslin. With very little practice and some small amount of dexterity it is possible to bring over the nose and mouth a doubled edge, making in all four folds of muslin through which the expired air may be filtered.

Deutsche medizinische Wochenschrift, January 23 and 30, and February 6, 1908.

A Bacteriological Property of Lecithin.—Bassenge says that emulsions of lecithin are to a pronounced degree lytic for typhoid bacilli. When brought into contact with a 1 per cent. water emulsion of this substance the bacilli immediately disintegrate. The organisms first shrivel and then break up into separate, highly refractive granules, as in Pfeiffer's experiment. In a 1-1,000 emulsion this result did not follow at once, and even at the expiration of thirty to sixty minutes, in addition to the shriveled and disintegrated bacilli well-preserved and motile organisms were present. A 1-10,000 emulsion manifested only traces of bacteriolytic power. Cultures made from these emulsions remained sterile at the strength of 1 per cent. and there was manifest inhibition in that of 1-1,000, while the 1-10,000 gave a result not appreciably different from the control. It was not found possible to render animals resistant to subsequent typhoid infection by injections of lecithin, but the substance was used to advantage in extracting the endotoxins for the purpose of making an immunizing serum. Cultures of the bacilli were flooded with lecithin emulsion, placed in the agitator, treated with chloroform, and the aqueous layer pipetted off. Guinea pigs treated with this toxin were not affected by infection twenty-four hours later, with several times the fatal dose of thyroid bacilli.

Intraperitoneal Rupture of the Bladder.—Nordmann says that the most important factor in improving the prognosis of this condition is that all patients with an abdominal contusion shall be brought to a hospital as soon as possible and that all manipulation, especially catheterization, shall be avoided. In the hospital a single catheterization may be performed, using all possible precautions against infection. A history of intoxication, particularly if abdominal trauma of any sort occurred while the patient was in this condition, is of significance. The earliest and most important symptom of intraperitoneal rupture of the bladder in addition to the ineffectual attempts to void urine, is the reflex abdominal rigidity. If the diagnosis of an intraperitoneal rupture has been made laparotomy should be performed as promptly as possible and the bladder rent be sutured. The abdominal cavity is best cleansed by means of irrigation with saline solution. If the suture of the bladder is successful, there is no suppurative peritonitis, and the intestines are not greatly distended, the abdominal incision may be completely closed. A gauze drain should never be placed in contact with the bladder wound, as this is a frequent cause of urinary fistula. If there is doubt as to whether the rupture is intra or extraperitoneal, it is advisable first to do a suprapubic cystotomy; if exploration of the bladder then shows that the tear is intraperitoneal a laparotomy may be performed.

Laryngeal Mirrors.—Leuwer says that, in spite of the advantages that Kirstein's method of direct laryngoscopy possesses, the fact that it is possible by its means to obtain a clear picture of the larynx in only about 25 per cent. of cases causes the old fashioned laryngeal mirror to remain the most effective instrument for the purpose. The difficulty which is inherent in this of becoming coated with moisture after a few moments of use, in spite of preliminary warming, has led to the suggestion of various expedients. It has not been found possible to produce a mirror of material which should not become coated with moisture on cooling. A number of solutions have been proposed for the purpose of covering the mirror with a film in which the moisture would be soluble and which would therefore prevent distortion of the image. Most of these, however, suffer from the disadvantage either of damaging the mirror or of being unpleasant to the taste and tending to induce gagging on the part of the patient. Another method of preventing the condensation of moisture on the surface of the mirror is to maintain its temperature longer than is the case with the ordinary instrument. The most satisfactory way of doing this is to use the mirror invented by Finkler, which is provided with a small flat chamber at the back of the mirror which can be filled with various heat retaining substances. Tests with several of these gave the following results. An ordinary mirror after a warming remained clear for one and a half minutes; Finkler's mirror empty, three and a half minutes, filled with water four and a half minutes, filled with sodium acetate six minutes, with powdered glass six and a quarter minutes, with a mixture of sodium acetate and powdered glass eight minutes, and with paraffin ten minutes. The author for over two years has used a mirror of this type filled with paraffin with great satisfaction, and states that its weight and size do not occasion inconvenience even in examining children.

The Detection of Blood in the Feces.—Citron discusses the reliability of the benzidin test and the technique of its application. He considers it advisable to make use of a larger portion of the stool than previous investigators have done and recommends triturating the entire defecation with acetic acid and taking 5 c.c. of this extract for the test. The extract is treated with 25 c.c. of ether, or preferably with carbon tetrachloride, which is more satisfactory on account of its noninflammable nature. The latter extract is evaporated to dryness in a porcelain dish, and the residue is then rinsed into a test tube with several cubic centimeters of glacial acetic acid. The reagent is prepared by adding a portion of powdered benzidin the size of a pea to several cubic centimeters of glacial acetic acid. This is added to the fluid to be tested, and the appearance of an intense green or blue color in a few seconds on the addition of several cubic centimeters of hydrogen peroxide indicates the presence of blood. Performed in this way, the reaction is far more delicate than the guaiac or aloin test, but it is necessary that the patients be placed on a diet completely free from meat for a period of two to four days before the stool is examined. Observations on a considerable number of patients suffering from various gastric disorders substantiated these views as to the reliability of the test. An interesting observation was the fact that in twelve cases of achylia a positive reaction was obtained seven times, a finding which leads the author to suggest that possibly the occult hemorrhages so demonstrated may have something to do with the anemia usually associated with this condition.

The Treatment of Puerperal Mastitis by Suction Apparatus.—Zangemeister, in discussing the treatment of this condition says that he considers it of great importance to stop nursing from both breasts immediately when the first signs of inflammation are noticed. The milk that accumulates is not removed from the breasts, for it is more logical to attempt to put the organ completely at rest as soon as possible. With the same end in view frequent doses of sulphate of magnesium are administered. It is equally important to secure mechanical rest for the gland by immobilization with bandages. Treated in this way only 19 per cent. of thirty-three cases went on to abscess formation, whereas in seventeen cases treated according to Bier's directions by means of suction, 64 per cent. suppurated. Apparently the suction tends to cause the process to progress more actively and it should not be resorted to during the earlier stages of the affection. When suppuration has already commenced the pus can be evacuated through smaller incisions if suction is used, but the method is not always effective and is less so the more recent the mastitis. The author believes it should be restricted to those cases of suppuration in which the inflammatory process is no longer extending. Even in favorable cases he does not think that the course of treatment is very much shortened by the suction method.

Pyocyanase Treatment of Diphtheria.—Muhsam describes observations made with this agent which is obtained from cultures of the *pyocyaneus pyocyanus* and consists of an enzyme which has the property of being lytic for diphtheria, cholera, typhoid, plague, and anthrax bacilli as well as for staphylococci, streptococci, and gonococci. Tubercle bacilli, however, probably on account of their fatty envelope, are resistant to the enzyme. The author found that *in vitro* the growth of diphtheria bacilli is inhibited and that even small amounts are sufficient to kill large numbers of the organism. In human therapeutics the application of the remedy by insufflation hastens the disappearance of the membrane and exerts a favorable effect on the general condition of the patients, who also experience much subjective relief. The exudate promptly disappears. Pyocyanase should be used only in connection with antitoxin, but the results of clinical tests so far justify further investigations with it.

Book Reviews.

Mosquito Life. The Habits and Life Cycles of the Known Mosquitos of the United States; Methods for Their Control, and Keys for Easy Identification of the Species in Their Various Stages; an Account Based on the Investigations of the Late James William Dupree, M.D., Surgeon-General of Louisiana, and Upon Original Observations by the Writer. By Evelyn Groesbeeck Mitchell, A.B., M.S. Illustrated. New York and London: G. P. Putnam's Sons, 1907.

This is a most readable book, as well as an instructive one, written in an easy colloquial style and dealing with a subject which unfortunately has a deep personal interest for everybody. But although the book is written in a popular style, the subject is treated in a thoroughly scientific way, and the work will be found serviceable by the specialist as well as by the lay seeker after information and the practical exterminator of the pests. The book is based largely on the notes of the late Dr. Dupree of Baton Rouge, with whom the author was associated for some time as entomological artist in the study of mosquitos, but it treats of all the species found in the United States—and their number is appallingly large—and not only those indigenous in that hotbed of mosquito life, the lower Mississippi Valley.

To the amateur who has the curiosity to make the personal acquaintance of the pests in his own locality the identification keys in Chapter XI. will be found indispensable: by means of them, with a little practice and experience, he will soon be able to determine to his satisfaction whether the creature whose life he has cut short by a well-directed slap is an *Ochlerotatus mitchellæ*, a *Grabhamia pygmæus*, an *Anopheles punctipennis*, or just a simple *Culex pipiens*. For the ordinary reader, however, the chapter of greatest interest will be that dealing with the means of destroying mosquitos or keeping them at a distance from the person. The public-spirited man who is working for the good of his neighbors as well as himself by ridding the locality of the insects, will also find assistance and direction here, but he will be discouraged to learn that, contrary to the popular belief, mosquitos can and do travel many miles from their birthplace and infest regions far removed from marshes and other breeeding places. They are also transported long distances by rail and steamer.

The genera best known by name are *Anopheles*, *Stegomyia*, and *Culex*, but it is interesting to learn that the celebrated Jersey mosquito, found from Long Island all down the eastern coast, being a salt-marsh breeder, is an *Ochlerotatus*, specifically *O. sollicitans*. Another species found in New Jersey, being a breeder in woodland rain-pools, is *O. trivittatus;* it is a fierce biter of the ankles. The Alaska mosquitos, which appear in countless swarms in the first mild days of spring, are, it seems, not an unmitigated evil, for the deer and other game are made so desperate by their stings that they rush to the rivers for relief and there fall a prey to the waiting and starving natives. But we cannot quote all the facts which the author of this entertaining book gives and can only refer the reader to the book itself, where he will find much that is curious and interesting regarding his mosquito tormentors.

A History of Nursing. The Evolution of Nursing Systems from the Earliest Times to the Foundation of the First English and American Training Schools for Nurses. By M. Adelaide Nutting, R.N., Superintendent of Nurses, Johns Hopkins Hospital; Principal of Johns Hopkins Training School for Nurses; President of the American Federation of Nurses; Member of the International Council of Nurses; and Lavinia L. Dock, R.N., Member of the Nurses' Settlement, New York; Secretary of the American Federation of Nurses and of the International Council of Nurses; Honorary Member of the Matrons' Council of Great Britain and Ireland, and of the German Nurses' Association. In two volumes. Illustrated. New York and London: G. P. Putnam's Sons, 1907.

The history of nursing may be divided into four periods: the pre-Christian era; the religious era, using the term in its technical sense as relating to the work of the monastic orders; the early secular period, and the scientific period, beginning with the establishment of training schools and the development of the strictly professional idea. The present volumes deal with the first three of these eras only, the history of the modern period being reserved for a future work.

In the section devoted to the pre-Christian period the authors review the history of the care of the sick in India, Ceylon, Egypt, Babylon, and Assyria, among the Jews, in Greece, and in Rome. In this period there was little or no distinction between the physician and the nurse, the same person not only caring for the sick, feeding them, and performing the many little offices contributing to their comfort, but also giving the appropriate remedies or conducting the sacrifices and the incantations designed to drive out the evil spirit which tormented them. With the advent of Christianity women began to take a leading part in the work of ministering to the sick and the wretched, a work which has been recognized ever since as one peculiarly their own. This work was begun by Roman matrons, early converts to Christianity, and was continued by the conventual orders. The conspicuous figures in the third, or secular period, are Fredericke Fliedner, the founder of the Kaiserwerth Deaconesses, and Florence Nightingale. There was also another less admirable type of professional nurse in this period, ignorant, careless, and dirty, yet often tender-hearted, devoted, and doing her best according to her lights—the Sairy Gamps. The beginnings only of the fourth period in the history of nursing, that of the training school, are touched upon in the final chapter of this interesting work.

The history of this branch of human activity is here presented in most readable and entertaining form. The work bears evidence of a vast amount of research and study of documents and records, the result of which has been the making of a book which both nurses and physicians will read with entertainment and profit. The illustrations are numerous and interesting, the typography and press work are excellent, and the book is one pleasing both to the eye and the mind. The authors deserve the thanks of their profession for this valuable contribution to the literature of nursing. The promised sequel, dealing with the history of training schools and of the scientific nursing of the present day, will be awaited with impatience.

Surgical Applied Anatomy. By Frederick Treves, Bart., G.C.V.O., C.B., LL.D., F.R.C.S. Sergeant Surgeon-in-Ordinary to H. M. the King; Surgeon-in-Ordinary to H. R. H. the Prince of Wales; Consulting Surgeon to the London Hospital; Late Lecturer on Anatomy at the London Hospital. Fifth edition, revised by Arthur Keith, M.D., F.R.C.S., Lecturer on and Senior Demonstrator of Anatomy at the London Hospital; Examiner in Anatomy, Royal College of Surgeons, England, and University of Leeds; formerly Examiner in Universities of Aberdeen, Cambridge, etc. Illustrated with one hundred and seven figures, including forty-one in colors. Philadelphia: Lea Brothers and Company, 1907.

Although this book is intended mainly for students preparing for final examinations in surgery, it has a useful scope far beyond and should be read with profit by all who practise surgery. It makes the dry details of anatomy interesting. The surface anatomy is carefully covered, then the parts beneath, teaching much that is often neglected by medical men. Anatomy should be learned as concerned in actual dealings with disease.

Cancer of the Stomach. By A. W. Mayo Robson, D.Sc., F.R.C.S. New York: Wm. Wood & Company, 1907.

In this excellent little book Robson describes all the conditions met with in cancer of the stomach and the best way to manage them. He is an advocate of early radical operations, which is quite natural. He believes in a precancerous state and expresses himself as follows: "Probably, if we could only find it, every cancer, whether External or internal, follows on a pre-cancerous condition. Such as cancer of the gall-bladder on ulceration produced by gallstones, cancer of the stomach on chronic gastric ulcer, epithelioma of the penis on irritation under a phimosis, cancer of the bladder on papilloma or an ulcer due to calculi, and cancer of the rectum and colon on stercoral or other ulcers."

Robson cites a few of his own radical operations for cancer of the stomach with permanent cure. Whenever the excision of the growth is impossible he recommends a posterior gastroenterostomy. The mortality of this operation amounted in his hands to 3.4 per cent.—a great contrast to the death rate in those cases a few years ago. Robson takes a hopeful view with regard to the ultimate curability of cancer of the stomach. He says: "After a careful analysis of all the cases operated on I cannot help feeling that far too gloomy a view is taken of cancer of the stomach, for, if the disease be caught early, and a wide excision performed, care being taken to remove the lymphatic area of the stomach with the glands along the lesser curvature, results even better than those I have just mentioned will be obtained. Our great hope of success, I venture to state at the risk of being accused of reiteration, lies in early and complete removal." All the operations performed on the stomach are minutely described. The book will prove very profitable reading for physicians and surgeons.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

214th Regular Meeting, Held on February 7, 1908.

DR. CHARLES STEDMAN BULL, PRESIDENT PRO TEM.

Two Cases of Exophthalmic Goiter.—Dr. ANDREW J. McCOSH said that these two patients, upon whom he had recently operated for exophthalmic goiter, showed the marked improvement which very often, in fact, generally, followed the operative treatment of Graves's disease, and they also illustrated how rapidly the improvement occurred. The first patient shown was a woman, twenty-nine years old, a native of Russia, who was operated on December 26, 1907. She had suffered from the disease for three or four years, and all the symptoms were present in an aggravated form. In her case, however, the exophthalmos was less pronounced than were the nervous and cardiac symptoms. Her pulse ranged from 120 to 160 per minute. She had tried all kinds of treatment, including Roger's serum, and prior to the operation she had spent six months in the Presbyterian Hospital without showing any signs of improvement. Since the operation she had gained in flesh and strength, and the exophthalmos was disappearing very rapidly. The cardiac and nervous symptoms had also improved.

The second patient shown by Dr. McCosh was a young man who was operated on one month ago. In his case there had been an extreme degree of exophthalmos, so that the eyes appeared to be popping out of his head. His pulse ranged between 120 and 170 per minute. Various methods of treatment, including Roger's serum, had been tried without effect. About 80 per cent. of the thyroid gland was removed, and since the operation the patient had gained twelve pounds in weight, his exophthalmos was less marked, and his tachycardia was lessened.

Dr. McCosh said he had operated on twenty odd cases of exophthalmic goiter, and as his experience with this class of cases increased, the more he favored operative interference. If the cases came into the hands of the surgeon during the earlier stages of their disease, the operative mortality would be very low. Probably three cases out of every four were relieved by operation, and certainly one-half were cured. Of his twenty odd cases, four had remained perfectly well for periods ranging from four to five years. There was a noticeable improvement almost immediately after the shock of the operation had passed off, and this improvement was continuous in the majority of cases. The mortality of the operation at present ranged between six and ten per cent. Among the cases that he had operated on there had been but one death: this had occurred in a woman upon whom he operated for the first time eight years ago, taking out one-half of the gland. Her symptoms recurred after two years, and he again operated, taking out most of the rest of the gland, and the patient died of acute thyroidism a few days after the operation. In former years the operation was not sufficiently radical, not enough of the gland being removed. In his later operations, he aimed to take out about 75 per cent. of the gland. It was not always an easy matter to take out just as much as one wished to do, because the gland was usually adherent and very vascular. Both the extent of the adhesions and the vascularity were generally much greater in cases of exophthalmic goiter than was apt to be the case in ordinary hypertrophies of the thyroid gland.

Dr. LEWIS A. CONNER said that a common difficulty connected with the various methods of treating exophthalmic goiter was that the benefit that resulted from them was often only temporary, and he was under the impression that this same objection might be raised to the operative treatment.

Dr. McCOSH, in reply to a question, said he was unable to state how many permanent cures he had had. Many of his patients had been lost sight of. He knew of four, however, who had remained well for periods ranging from four to nine years. During the past three months he had operated on seven patients. In all of these the benefit derived from the operation was already very evident. With one exception, improvement in the three cardinal symptoms was pronounced. In one woman, however, the delusions of persecution etc., still persisted.

Dr. EDWARD G. JANEWAY said that of all disorders, exophthalmic goiter was apparently the one in which hospital treatment was particularly contra-indicated, because among hospital surroundings it was practically impossible to obtain consistent therapy in the care of those patients, and the excitement they were subjected to did not contribute to their welfare.

Some Observations of the Effects of Tobacco in Surgical Practice.—By Dr. C. BOLTON BANGS. (See page 421.)

Dr. GEORGE L. PEABODY said that, while everyone had probably seen instances where the sudden withdrawal of tobacco was followed by the advent of nervous symptoms, this had not been a very frequent occurrence in his experience. He regarded Dr. Bangs's observations as of great interest. It was scarcely feasible to let people who were very ill smoke in hospital wards, but, on the other hand, the period of convalescence from a surgical operation was clearly not the time to choose for interfering with any drug habit. In referring to the rapid effects of inhalations of tobacco smoke, Dr. Peabody said it was a well-known fact that morphine or any other substance in solution introduced into the air passages, and especially into the trachea, was rapidly absorbed by the blood. Absorption by that method was even quicker than by subcutaneous injection, and that this might account for the rapidity of effects produced by inhaling the smoke of a single cigarette.

Dr. A. ALEXANDER SMITH said that, from a medical standpoint, he was thoroughly convinced that there was a good deal in the suggestion made by Dr. Bangs in connection with the effect of the withdrawal of tobacco, and he considered it a good therapeutic measure in dealing with patients who had been addicted to the use of tobacco, to allow them to resume the habit in very early convalescence, thus not only adding to their comfort, but producing a very perceptible beneficial influence on the heart. The explanation of the latter was probably found in the influence of tobacco on the sympathetic nervous system.

Dr. JANEWAY called attention to the fact that tobacco increased the blood pressure, and in that way its beneficial effects might be explained in some cases. He knew of instances, however, in which no apparent effect had been produced by the sudden withdrawal of tobacco in persons who had been addicted to its excessive use for many years.

Dr. CHARLES STEDMAN BULL said he had noticed the depressing effect of the loss of tobacco on chronic smokers in operative cases. He recalled one case of senile cataract in a perfectly healthy man who had been a smoker all his life. After the extraction of the cataract it was noticed that the man was restless and suffered from more or less insomnia and pronounced disturbance of his digestion. Acting on the supposition that his symptoms were due to his confinement to bed, he was allowed to sit up in an easy chair on the third day. An inspection of the wound at this time showed that it was wide open, without any secretion or the slightest evidence of any inflammatory process. After eight days the wound was still open without any reason to account for it. It was then learned that he had always been a heavy smoker, and he was thereupon given permission to resume his pipe. That night he slept soundly for the first time since the operation, and on the following day the wound in the eye was found to be healed from end to end. Dr. Bull said he knew of several instances parallel to the above

Dr. Lewis A. Conner, in reply to a question as to whether nicotine was now ever used medicinally, said there was some doubt as to whether nicotine was the only or even the chief agent in producing the sedative effects of tobacco smoking. There were probably other factors, the influence of which was not yet thoroughly understood.

Dr. Bangs, in closing, said the main object of his paper was to call attention to some of the conditions following operation that were not explicable on strictly surgical grounds, and the result of his experience had led him to believe that they were in some instances due to the sudden withdrawal of tobacco in chronic smokers. In connection with this general subject he mentioned the fact that he had recently read an article in the Medical Record in which glycosuria was attributed to the use of tobacco.

Preliminary Report of a Case of Cerebrospinal Meningitis of Streptococcus Origin Apparently Cured by Subdural Injection of Anti-Streptococcus Serum.—By Dr. George L. Peabody. (See page 423.)

The Mackenzie Ink Polygraph.—Dr. Lewis A. Conner demonstrated this instrument.

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held January 8, 1908.

August Hoch, M.D., President, in the Chair.

Psychogenesis in Dementia Præcox.—Dr. August Hoch of Bloomingdale Hospital, White Plains, read this paper. Building upon the work of Freud, Jung, Bleuler, and Adolf Meyer, he tried to show by an analysis of two cases, fully reported, how conflicts or longings, which had existed for a long time, gradually grew until they became dominant. By an analysis of the patient's life certain traits were demonstrated as well as certain external conditions which accounted for this gradual growth. It was shown how similar conditions existed in simple paranoiac states, but that in dementia præcox the situation was different for the reason that the mental trends represented by the conflicts or longings were of such a nature that there was a strong aversion on the part of the personality to allow them to become fully conscious. For that reason they were suppressed and only manifested themselves through substitutions or through the appearance in the minds of portions of the disturbing trends, or peculiar incomprehensible reactions. Such manifestations of undercurrents were then logically disconnected; the thoughts, delusions, hallucinations, and acts which thus arose had no conscious motivation; the natural harmony between effect and ideation was disturbed, etc. If this became fixed the mental mechanism no longer dovetailed with life and reality, the interest vanished, and a certain form of dementia developed. It was, of course, not claimed that this was the only explanation of the deterioration, but probably an important factor in some cases. In other words, it was shown in the two cases that the clinical picture was explained by the conflicts and the reactions to it, that the conflicts had existed long before and were of gradual growth, while the latter could be accounted for by the absence of sufficient balancing factors. Of interest is also the fact that one of the cases, which presented a very perplexing clinical picture, was, by careful psychoanalysis, reduced to a comparatively simple situation, and that it was possible to use this knowledge in the treatment with very gratifying results, the improvement being always so clearly related in time to the therapeutic talks that an accidental coincidence seemed hardly probable.

Dr. Adolph Meyer emphasized the necessity of studying the psychogenetic data. The records of Dr. Hoch, just as they were, spoke more convincingly than any comments. The aversion of most physicians came from their judging on the ground of poorly taken histories. The patients often preferred the method of ignoring the sore points; but these cases presented totally different figures concerning relapses than those who were able to enter squarely upon a psychoanalysis. The choice of a helper was often difficult. In one of Dr. Meyer's cases the mother had a very good grasp on the factors which led to the disorder, but now as little talent in correcting them as she had had in preventing the breakdown. Physicians were slow about seeing that many things they demanded from families and patients on the ground of "common sense" were really good illustrations of beginnings in the management of psychogenic factors. One of the most direct acknowledgments of the principle that had come to his notice lately was a statement of Dr. H. S. Noble of the Connecticut State Hospital at Middletown, in which he said: "The constant personal attention of a congenial, sensible companion can do more toward the restoration of curable forms of mental disease than any other agency with which we are at present acquainted."

Dr. William L. Russell of Poughkeepsie, N. Y., was confident that there must be considerable value in such analyses of cases as Dr. Hoch had been able to make—analyses which could hardly be hoped for except under the most favorable conditions—and while the method might not explain the nature of the disease, it certainly gave promise toward enabling one to point out preventive and therapeutic measures. Dr. Russell asked Dr. Hoch to explain his views as to how the "longings" operated in bringing about the final breakdown.

Dr. Smith Ely Jelliffe said he had had the pleasure a year ago of listening to Dr. Hoch's initial paper, with which he was in entire accord, and at that time he had expressed the belief that if one was able to appreciate the character of these conditions early enough, by methods so ably outlined by Dr. Hoch—methods in which there was not the slightest doubt that the right track was to be found—the results pointed out in the second case would follow. He was glad the therapeutic method so amply verified the hypothesis laid down by Dr. Hoch. He agreed with Dr. Meyer concerning the desirability of getting at the environment from an inside point of view. Many dementia paranoides cases were made so largely by the stupidity of the family. In this connection he mentioned a family which had come under his observation, in which there were six children, every one of whom exhibited the general trend of this type of cases. One particularly showed the paranoid character. This youngest child exhibited the exact equivalents of the second case of Dr. Hoch's paper. He had been unable to explain the genesis of the condition in these children until he met the mother, when, after four hours' talk with her, it became evident that her maladjustment to life, her strained interpretations of the situations which came up in the children's lives and in her own life, rendered her the most important factor in the genesis of the condition, and yet she was the most intelligent and best able of all those involved to rectify the maladjustment in the lives of the children. Regarding the general features of which Dr. Hoch had spoken, he believed there was no occasion for a discordant note.

Dr. Pearce Bailey asked Dr. Hoch whether the memory of the sexual trauma in the second case had been obliterated from the consciousness, and also what method he employed to elicit the history thereof. It was absurd, of course, for one who had not seen the cases to criticise the diagnosis, and yet the question might arise as to the second case not having been one of dementia præcox. It had many points in common with cases of a hysterical character with a history of sexual trauma. The sudden change for the better after a single explanatory talk was contrary to the ideas he had had of dementia præcox. If a cure could be effected so rapidly, it would seem that some of the accepted classifications would have to be materially

changed. Throughout the whole range of psychiatry, both in the actually insane and in the unstable, the importance of a single emotional event in the life of the individual was commanding more and more attention. A powerful emotion of a suggestive character might spur on to immediate action in the unstable. An emotional event also might make its deep impression on personality, lie dormant for years, and then spring forth again, giving a dominant note to a psychosis. He cited the case of a man who, when age and ill health came on, reverted to an incident which had made a deep impression on him as a boy, and which had been forgotten all through the years of health and prosperity. As the study of psychiatry proceeded, the speaker thought, the effect of emotional events upon different classes of individuals would possibly form a better method of classification than the cruder one of grouping by diseases. In conclusion, he asked Dr. Hoch if it were not easier to get at and benefit the disturbances resulting from emotional complexes if the patients were not fully aware of them.

Dr. Maurice C. Ashley of Middletown, N. Y., said that alienists were coming more and more to realize that each case of insanity is a law unto itself, demanding a most careful analysis if one's full duty was to be done by it. They must not be content when they obtained sufficient facts for a diagnosis, but they must go further; they must learn of every factor which had had to do with the mental and physical health of the individual in order that they might know whether or not any of these factors have had to do with the developing psychosis, and whether they could be eliminated. The tendency in the past had been to look only for sufficient facts for diagnosis and classification, rather than to study the individual in an endeavor to get at the bottom of *his* particular difficulties, as Dr. Hoch had done. The general practitioner and specialist who saw these cases before the psychosis had fully developed had an excellent opportunity to study and treat such patients successfully. When they came to the state hospitals the psychosis had usually advanced so far that it was much more difficult for the physician to get at the bottom of the psychosis and for the patient to get right with himself than it would have been at an earlier stage.

Dr. A. R. Diefendorf of Middletown, Conn., said the development of this new field in psychiatry had been aided by an appreciation of the fact that one's duty in a hospital must not be scattered over the whole multitude, but must be centered on the few who could derive benefit from one's labors. He cited the case of a girl who exhibited the same features presented by Dr. Hoch's second case. The true significance of the sexual trauma was brought to light by the sensations which the patient experienced while under the influence of gas for the extraction of two teeth. It was difficult to know just how to deal with these cases, just when to attack the ideas and just when to leave them alone, and to be sure that one would do good and not harm. Success depended somewhat upon the intuition of the operator. He had noted that it was difficult to make progress with men and boys, who did not seem to have the same experiences as women and girls. He cited the case of a young man with whom he felt sure there were hidden psychogenic influences, but he could not get at them. Nevertheless, intelligent companionship and life in the open for three months had seemed to effect a cure.

Dr. L. Pierce Clark said, in searching for the causative agent of his new eye syndrome in dementia præcox, he was impressed that the psychosis had principally a somatic cause. To determine this as well as the psychogenetic factors, he believed an extra-asylum study of the disorder was absolutely necessary. The burden of the solution of the problem rested with the physician in private practice. In order to run to earth these causative factors he had instituted a method of careful mental and physical analysis of all cases of neurasthenic habits in adolescents applying at the Nerve Department at the Vanderbilt Clinic. An analysis of the cases is made independent of the question whether the symptoms point directly to a præcox psychosis or not. The final outcome of a number of such cases would prove of great value, whether they deteriorated into the dementia præcox or not. He had been urged to do this, furthermore, as there seemed to be a pressing public need of a study and consideration of normal and pathological habits of adolescents. He hoped the future might produce specialists in adolescents, as Stanley Hall had also suggested.

Dr. G. H. Kirby had met few cases in which the analysis could be pushed to such completeness as Dr. Hoch had so skillfully carried it in the cases reported. The unraveling of the psychogenic elements entering into a case certainly threw an important light on the symptomatic picture and explained many reactions that would otherwise have to pass merely as peculiar, erratic, senseless, or not understandable—features that were usually referred to as characteristic for dementia præcox. A review of the cases exhibiting the dementia præcox form of reaction seems to show that the deteriorating cases had nearly always given warnings of rather grave constitutional anomalies, such as lack of natural instincts and perversion of normal interests or various defects in character and judgment. On the other hand, cases showing a dementia præcox-like outburst, but terminating in *recovery*, had, as a rule, shown none of the serious defects just mentioned. So, after all, one must be guided largely in the prognosis by the previous standard and efficiency of the individual.

Dr. James J. Putnam of Boston said that his own belief for a long time had been thoroughly in accord with the conclusions of Dr. Hoch, namely, that the environment of the patient and the reaction to the environment might be the controlling influences in a given case. He was glad to hear Dr. Hoch emphasize this point. The doubt raised by Dr. Bailey as to the diagnosis of the second case could only be solved by determining what dementia præcox was, and that was impossible. In Jung's book reference was made to "fixed mental reactions." This recalled the fact that von Basch and others had spoken of the tendency to arterial spasm as being the first thing which in some way leads to arteriosclerosis, a functional condition leading to a structural condition, but perhaps not always to an equally unfavorable structural condition. We would like to believe and might fairly hope that the best sorts of influences, applied sufficiently early, might change the whole trend of subsequent events. In the Massachusetts Hospital out-patient department several trained women were employed to do the very sort of thing Dr. Clark was having done at the Vanderbilt Clinic. It was their duty to learn as much as possible about the family and the home life of such patients. An effort was also being made to study the children of psychopathic families. If dementia præcox was to be arrested the attempt must be begun early and by aid outside the family.

Dr. Hoch, in closing the discussion, said that Dr. Bailey and Dr. Putnam had raised the question of the differential diagnosis between dementia præcox and hysteria. Of course the differential diagnosis was sometimes difficult, all the more since, as yet, the relationship of dementia præcox and hysteria were not understood. There were cases which began like hysteria and terminated like dementia præcox, and, on the other hand, he had under observation a case in which the disease began as a typical dementia præcox, with a long history of wholly uncorrelated delusions and hallucinations, followed by a catatonic stupor of about a year's duration, but a patient who now had lost practically all dementia præcox symptoms and manifested only something like an astasia-abasia. In regard to the transition from functional to organic changes,

there were certain analogies in general medicine. The speaker thought it was something of this sort to which Dr. Meyer referred in his paper on dementia præcox, when he said that misapplication of instincts and faulty habits were bound to undermine not only the functional mechanism, but the organ itself. Questions had been asked about the method of psychoanalysis. This varied according to circumstances. Dr. Hoch first thought that association experiments were necessary in each case, but this was evidently not so. Very often the symptoms of the disease, the delusions, hallucinations, or peculiar acts, or perhaps an accidental remark of the patient, gave a sufficient lead as to the direction in which it was necessary to probe. The matter was always tedious and had to be taken up again and again, and one sometimes found the way blocked entirely and had to leave the analysis for the time being. Sometimes, as suggested, the question arose whether one had a right to proceed with the analysis. He was inclined to think that the danger of talking about personal matters was, on the whole, overrated. Nevertheless, it was a matter which needed a good deal of consideration, and which the skill, tact, and experience of the observer had to decide in each case. Certainly it is often unnecessary to go into details of subjects which are unpleasant, if these details are not absolutely essential, no matter how much our desire for accuracy and completeness would tempt us to proceed.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENITOURINARY SURGERY.

Stated Meeting, Held December 18, 1907.

DR. FOLLEN CABOT, CHAIRMAN.

A Case of Surgical Kidney, with Specimen.—Dr. JAMES PEDERSEN reported this case. The patient was a spare man, 22 years old, single, who came under the speaker's observation July 30, 1907, with the following history: Since his tenth year he had had occasional attacks of scalding urine and pain in the penis, with pain in the region of the left kidney. The intervals between these attacks had been about one month; sometimes longer. The duration of the attacks had varied from a few days up to ten days. It was said that his urine always had a bad odor, even when fresh. Its sediment was described by the family as having been pinkish-brown and coarse. Exposure to cold and undue fatigue were mentioned as exciting causes of these occasional attacks. In the latter part of May, 1907, the patient developed a urethritis. He took capsules of his own prescribing, and the discharge ceased in a week. About a week later, namely on June 6, while surveying in good weather, he developed great frequency of urination, with tenesmus. That night he had coitus. The discharge reappeared the following morning; the frequency and tenesmus increased, and forty-eight hours later terminal bleeding was noticed. On the following day, June 9, considerable pain developed in the left kidney region. The next day he went to bed and remained there for three weeks, during which time the frequency, tenesmus, and kidney pain continued, and a milky urethral discharge was apparent off and on. Finding that he was not improving, he decided to return to work. After one week he was again compelled to take to his bed. On the morning of July 9 he was awakened with a sudden, very severe pain in the left kidney region, and he noticed that his urine was thick and extremely offensive. The kidney pain became continuous and the frequency and tenesmus increased. After he had been in bed one week the discharge ceased, but all the other symptoms remained unabated. Between July 8 and 30, when Dr. Pedersen first saw him, he had lost thirty-two pounds. He gave no history of chills, but had had profuse sweats, with undoubted rise of temperature. There was no personal family history of tuberculosis. There was no history of scarlet or typhoid fever or of gastrointestinal disturbances. The patient was markedly anemic and emaciated. The urine was loaded with pus of a dirty, grayish color and had a putrid odor. The left kidney was palpable and tender. After the patient had been carefully nursed for one week a rapid nephrotomy for drainage was performed. A large pus sac was found, from which a volume of extremely offensive pus was evacuated. The patient rallied satisfactorily from the operation and began at once to gain in health and strength. After about two weeks, however, the kidney tissue showed a persistent tendency to close, and the urine, which had been perfectly clear during those two weeks, again became charged with pus from the diseased kidney. All attempts to maintain drainage by way of the loin failed. Finally, on October 29, 1907, the patient being in fairly good condition, nephrectomy was performed. The shock was profound, but he responded to the active treatment employed and rallied within four hours. He was making a satisfactory recovery. The uranalysis prior to the nephrotomy was as follows: Color, amber; turbid, with a heavy gray precipitate; strongly acid; albumin present; no sugar nor indican; urea, 11 gr. per ounce; a small amount of mucus; a large amount of pus, forming almost the sole precipitate; no blood; no casts; large numbers of bacteria; no crystals; abundant amorphous deposit. The bacteriological examination of the heavy sediment showed short chains of streptococci, staphylococci, and a few diplococci. No gonococci; no tubercle bacilli. The report of the pathological examination by Dr. Sondern was as follows: "The capsule is not thickened, but is infiltrated with red blood cells and is separated from the cortex in places by considerable hemorrhage. There are large areas of hemorrhage in the cortex and medulla near the pelvis. The blood-vessels are congested. The glomeruli are congested and some of the capsules of Bowman contain blood. The cells in some of the convoluted tubules are swollen and almost occlude the lumen of the tube; in other tubules the epithelium is disintegrating. Section into the pelvis shows desquamation of epithelium. Beneath the epithelial line is a thick zone of round cells which is vascular and congested. Beneath the zone of round cells is a thick layer of dense fibrous tissue which contains many accumulations of inflammatory round cells. There is some superficial necrosis and hemorrhage in the pelvis. No tubercles found. Diagnosis: Chronic and acute parenchymatous nephritis; ulcerative and hemorrhagic pyelitis." The precise etiological factor in this case, Dr. Pedersen said, could not be determined. From the history, however, it was fair to assume that this patient had been carrying a chronic pyelitis, probably due to the colon bacillus, for ten years, and that from his posterior urethritis he developed an ascending infection which brought about the lesion that endangered his life.

Dr. MARTIN W. WARE suggested that the cystitis in this case might have been due to a descending process from the kidney.

Dr. PEDERSEN replied that the patient had had no symptoms of cystitis until after he had contracted urethritis and the posterior urethra had become involved. After that he developed this sudden attack of kidney pain. He therefore believed that the kidney abscess was the result of an ascending infection.

Dr. WARE called attention to the fact that in the specimen shown by Dr. Pedersen the lesion was in the cortex of the kidney rather than towards the pelvis. This seemed to indicate that the infection was hematogenous, because in the ascending variety the pelvis was more apt to be involved.

Dr. PEDERSEN said that possibly there was both a hematogenous and an ascending infection, though Dr. Sondern, in his pathological report, did not make any mention of infarcts.

Dr. FOLLEN CABOT said the fact that the man improved to

such an extent after removal of the kidney made it appear more like a descending than an ascending infection. In cases of ascending infection the bladder trouble was usually of long standing.

Dr. Victor Pedersen exhibited an irrigating sound and an ointment applicating sound for the deep urethra.

Dr. A. A. Berg, in discussing reflex anuria, to which Dr. Pedersen had referred, said he did not think there was such a thing. In the cases that had come under his observation, he could not recall a single instance in which the anuria was secondary to stone or traumatism affecting one kidney, and he was inclined to believe that the suppression of urine was the result of a septic condition induced by the operation, or, perhaps, as French explained it, the destruction of the cells of the injured kidney produced a similar or so-called cytotoxic action on the cells of the opposite kidney. The speaker said he thought it was about time that we arrived at some definite conclusion in regard to the presence or absence of the so-called renorenal reflex.

Dr. Robert H. Greene said there were certain instances where the anuria was apparently due to shock following operation. The condition was also not uncommon in hysterical women, and was apt to be associated with floating kidney.

Dr. Cabot asked Dr. Berg how he would account for the immediate anuria following operation. In one of his cases of attempted cystoscopy in which he even failed to see the bladder there was a resulting anuria lasting twelve hours. In that instance there was no suspicion of sepsis.

Dr. Berg raised the query whether an anuria immediately following cystoscopy, such as that referred to by Dr. Cabot, should be regarded as one of true anuria? Such a phenomenon was not infrequent after urethral catheterization; it was perhaps due to a temporary nervous shock, and the patients apparently did not suffer from it. The type of anuria he had reference to was that in which there was complete anuria after an injury or operation affecting one kidney, and the question arose whether we were to ascribe such anuria to a reflex origin or to a septic or cytotoxic effect.

Dr. Francis C. Edgerton said he had never made applications of ointment to the urethra, because he had always believed that such applications would simply cover up the disease. They surely did not mix with the urine, and, unless they were composed of remedies that dissolved very quickly, they would exert little beneficial effect. The speaker said that in cases such as those described by Dr. Pedersen, where the trouble was confined to the posterior urethra, he had had good results from the use of ichthyol in glycerin. He was inclined to believe that glycerin acted very much as did a tampon and exerted a hygroscopic effect, thus reducing the inflammation, while the ichthyol had a stimulating effect. Dr. Edgerton said that the irrigating sound shown by Dr. Pedersen would doubtless prove a very useful instrument in old stricture cases with urethral pockets left by the passage of an instrument or following a perineal section; in those cases he had often found it exceedingly difficult to introduce a rubber instrument.

Dr. James Pedersen said he agreed with the previous speaker that the irrigating sound would prove a very serviceable instrument, particularly as it accomplished a double purpose and thus saved instrumentation, which was an important point in dealing with the urethra. In regard to the second instrument shown, Dr. Pedersen said he had never used ointments in the urethra and had been rather opposed to that method of treatment. At the meeting of the American Genitourinary Association two years ago, Dr. Hugh Young showed a somewhat similar instrument, which met with an indifferent reception. Dr. Pedersen called attention to the fact that unless the ointments applied to the urethra would liquefy in fluid the temperature of the urine in the bladder, portions would be likely to pass backward into the bladder and form a nucleus for stone.

Dr. Robert H. Greene said that some years ago he made applications of ointments of various kinds to the urethra by means of the old-fashioned grooved sound, with indifferent success. The irrigating sound shown by Dr. Pedersen doubtless had its uses in certain cases. In cases such as those referred to by Dr. Edgerton, where superficial urethral pockets interfered with the passage of a soft catheter, the speaker said he had successfully employed the French instruments with the bulbous end.

Dr. Edgerton said the cases he had reference to were those in which the pockets had formed after stricture or prostatic abscess where the abscess had either ruptured or had been opened into the urethra. He recalled two such cases where he had found it absolutely impossible to obtain entry beyond the prostatic urethra until the finger had been inserted into the rectum and had raised the end of the catheter.

Dr. Victor C. Pedersen said the objections raised against the use of salves in the urethra did not hold good in all cases providing the base of the ointment was lanolin and glycerin, about 3 or 4 to 1. Of course he did not advocate their use in cases where germs in the shreds were still present, but salves should be tried in those desquamating conditions where fluid applications were unsatisfactory. The speaker said he did not favor the use of urethral bougies; these were too hard, and acted as foreign bodies in deep urethra. The use of ointments in the urethra in well selected cases, and after other well-known methods of treatment had failed, he was convinced had a definite though limited field of usefulness. The irrigating sound would be found useful in certain cases, usually post-operative ones, where it was impossible to introduce a soft instrument into the bladder. He said he had seen two cases of reflex anuria. In one case a sound had been passed and an effort was then made to pass a soft rubber catheter. The man returned on the following day and stated that he had had a chill and a rise of temperature and that he had passed no urine until very late the previous day. He was given quinine and urinary antiseptics and the anuria disappeared. The other case was that of a young man who had had his prostate removed for tuberculosis; after the operation, every time an instrument was passed through the urethra, even a soft catheter, he would have a rise of temperature to 104° or higher, with total suppression of urine, and a delirium almost amounting to mania. It was suggested that there was some trouble with one of his kidneys, and an *x*-ray picture showed a stone in the right kidney, which was subsequently removed.

Dr. Berg said he knew of one case where death had occurred twenty-four hours after the passage of a soft catheter through the urethra, the fatal result being due to a septic condition that immediately followed the urethral instrumentation. He had seen a temperature of 105° develop within three hours after a laparotomy, with septic peritonitis, and death within twenty-four hours.

Dr. James Pedersen said there was no question that these septic processes could occur with exceeding rapidity, the patient sometimes being overwhelmed by them and dying suddenly. He recalled the case of an old man who died within a few hours after being catheterized for urinary retention, and that of a young man who died eight hours after a simple internal urethrotomy. In both instances the patients were apparently overwhelmed by some form of sepsis. The speaker said he believed in the so-called reflex type of anuria following instrumentation of the urethra, and thought it could be classified as a species of traumatic shock which results in a total inhibition of the kidney function by way of the nervous system.

SECTION ON SURGERY.

Stated Meeting, Held January 10, 1908.

DR. CHARLES H. PECK IN THE CHAIR.

Four-Ounce Brain Tumor.—Dr. JOHN F. ERDMAN presented this case and specimen. This woman had one arm completely paralyzed from the shoulder down. There was no involvement of the lower extremities. Four or five days after the removal of the brain tumor she noticed a returning sensation, as if something burning, and was able to raise the arm from the side of her body. There was a rapid return of function in the upper extremity.

Vaginal Drainage of the Ureter After Nephrectomy.—Dr. A. ERNEST GALLANT presented a patient whom he saw December 29, 1905. She was then troubled by a cystic tumor lying on the left side of the abdominal cavity with its center opposite the umbilicus, movable up and down two or three inches and seeming to have arisen from the pelvis. An anterior exploration showed it to be retrocolonic, and made up of a dilated kidney and pelvis. On January 17, 1906, the pelvis of the kidney was opened and emptied of from 1,000 to 1,500 c.c. of urine. On exposing the ureteropelvic junction the obstruction was found to be due to an S-like bending of the ureter, bound down by dense adhesions completely shutting off the urinary flow. As soon as the bands were loosened a probe could be passed through the ureter to the bladder. Owing to the large size of the kidney no attempt was made to suture it, but gauze packing was placed under it and the urine flowed freely for several days until the packing was removed. Later the kidney seemed to drop, and the obstruction recurred on April 25, 1906, and then it was deemed advisable to remove the kidney, leaving part of its pelvis and the ureter. From that time until September 18, 1907, there was more or less discharge from the loin, evidently mixed with urine. A catheter was inserted into the ureter and easily passed to the cavity in the loin, and with this as a guide, stiffened by a metal probe, an incision was made through the vagina exposing the ureter. While endeavoring to draw down the ureter with mousetooth forceps before resection, the bladder was torn into and the finger was used to hook down the ureter, rendering resection quite easy. The ureter was cut off about an inch from the bladder, and the pelvic end was brought down into the vagina and sutured in such a way as to expose its lumen in the vaginal vault. Two sutures were inserted through the vaginal wall and the bladder end of the ureter closing it off. On September 30, 1907, the vesicovaginal fistula was closed by silk-worm sutures. Last week the lumbar sinus closed. A small papilla in the vagina marked the site of the ureteral implantation.

Kidney Cases Presenting Some Unusual Features.—Dr. A. A. BERG presented these patients.

Tuberculosis of Kidney.—The first case was that of a woman, 28 years old, who had suffered from renal tuberculosis for one year, the disease running its ordinary course of frequent and painful urination and cloudy urine. At some hospital in Brooklyn a suprapubic cystoscopy was performed, but evidently the findings were not appreciated. The suprapubic wound was drained and the bladder irrigated, but with no improvement. The fistula closed when the suprapubic drain was left out, a rather unusual thing. She was admitted to Mt. Sinai Hospital last autumn with a slightly discharging suprapubic gstula. She had all the ordinary signs of kidney tuberculosis as usually found. A cystoscopic examination showed large ulcerations of typical type. The urine contained large quantities of thin pus and tubercle bacilli, which at once cleared the diagnosis. Ureteral catheterization showed the urine from the left kidney to be clear, but containing albumin and casts. The question arose whether we were justified in removing the diseased kidney on account of the apparent disease of the other organ. The usual procedure was pursued in this case for determining the functional capacity of the left kidney, viz., estimating the amount of urine that kidney was excreting, its character, urea contents, etc., and from these data we made up our minds that the left kidney was secreting sufficient urine to warrant the removal of the diseased kidney. The method employed in this case was what Dr. Berg said he wished to call attention to. In cases where there was considerable perinephritis with dense adhesions, there was always a great deal of bleeding with tremendous shock to the patient and probably many cases had been lost from the extent of the procedure and the loss of blood it entailed. To avoid these risks it was suggested that, instead of doing the nephrectomy in the usual manner, to cut through the fibrous capsule and shell the kidney out of the latter. This took but five or ten minutes and there was practically no bleeding. A rubber ligature was passed around the pelvis of the kidney and its amputation performed. A subcapsular nephrectomy was the operation done.

Total Anuria from Obstruction of One Ureter.—The second case was that of a woman who came into the hospital last summer. For a number of years past she had complained of attacks of kidney colic on the right side. About one week before her last seizure she had a particularly severe attack of kidney colic, and again located upon the right side; it was not accompanied by hematuria. The pain increased for one week. Suddenly she noticed that she voided no urine and then she applied for medical treatment. In spite of the use of all the customary methods for stimulating the secretion of urine she passed none for seventy-two hours. There were no signs of uremia. She had some temperature. Her physical condition was good. She was immediately cystoscoped and the ureters catheterized. No obstruction was present in the ureters up to the kidney pelves, and no urine came from the kidneys through the ureteral catheter. The kidneys themselves could not be palpated; they were not enlarged. There was no tenderness on palpation. Upon exposing the kidney of the right side it was found to be lying in a transverse position, with its pelvis upward and the cortex downward, the ureter passing over its inner pole. The kidney was stony hard and there was some perinephritis. It was moderately enlarged and there was some congestion. It was easily restored to its normal, the up and down position. No calculi were present. Incision into the kidney in the usual fashion was made and a drainage tube was introduced into its pelvis. Immediately the urine commenced to flow from the tube in large quantities. The next day the patient passed urine through the bladder and secreted abundantly through the drainage tube. The post-operative course was somewhat complicated by a pyelitis and subsequent abscesses in the kidney. She made a gradual but uninterrupted recovery.

Unilateral Surgical Kidney Following Urethral Instrumentation.—The third patient he presented was a boy, 15 years old, who had had a spina bifida successfully operated on. He suffered from incontinence of urine and for this he applied to a city hospital for treatment. It was suspected there that he had stone in the bladder and an examination was made with the searcher under strict antiseptic precautions. Nevertheless in twenty-four hours he was seized with chills, a rapid and high rise in the temperature and marked prostration. Ten days later he was brought to Mt. Sinai Hospital. He then had high temperature, chills, was in a poor physical condition, and there was a large amount of pus in his urine. The right kidney was enlarged and tender. Incontinence was present. The meatus and urethra were too

small to permit of a cystoscopic examination, and they were compelled to content themselves with a palliative course of treatment and observation. The high temperature and chills continued, with marked pain and tenderness and enlargement of the right kidney. A few days after they decided to cut down upon it. The right kidney was found to be moderately enlarged and containing many miliary abscesses. The pelvis was much dilated and contained purulent urine. The pelvis of the kidney was drained, hoping that the abscesses of the kidney would yield to more conservative treatment than a nephrectomy was presumed to give. With a nephrotomy and drainage the boy improved. The temperature fell to 100°. Later the temperature rose to 104° and 105°, his physical condition became worse, and they had to resort to further operative interference. In order to determine the presence and condition of the left kidney, it was cut down upon, for the urethra was too small to permit of the introduction of a cystoscope. It was found to be of normal size but surrounded by a perinephritis. Acting upon the suggestion of Dr. Gerster, he introduced a trocar into the pelvis of the kidney, hoping that he might thus get a sufficient amount of urine for an examination. But in this case the trocar became plugged with blood and no urine was obtained. He could not understand why there should be so much of a perinephritis, but he supposed the condition of this kidney was the same as the other. He did a subcapsular nephrectomy, as in the above case. There was practically no shock and the boy rallied well. The temperature had been normal since, and he now was in good physical condition. Numerous abscesses were found to be present in the cortex of the kidney.

Nephrolithiasis in Horseshoe Kidney.—The fourth case was that of a man who gave the ordinary history of a nephrolithiasis. The *x*-ray showed a stone in the cortex of the right kidney. A cystoscopic examination was not done, reliance being placed on the *x*-ray findings, a very unwise procedure. The right kidney was cut down upon and an intense amount of perinephritis was noted. On separating the adhesions he found he was dealing with a horseshoe kidney fused at the lower pole. It was impossible to raise the kidney to the wound. Needling the kidney did not reveal the stone and inasmuch as it was impossible to deliver the kidney into the wound the search for the calculus was ineffectual. However, the patient subsequently passed a stone which, in all probability, the manipulation had started down into the pelvis.

Rupture of the Kidney.—The fifth case was that of a woman, whom the speaker showed to demonstrate the conservative course pursued in a case of the severe rupture of a kidney caused by being run over by an automobile. The kidney was torn in an oblique fashion from the upper junction of pelvis with cortex to its middle and lower third. A second rent was in a longitudinal direction along the inner border from the pelvis to the lower pole. The patient was seen four hours after the injury. The kidney was delivered into the wound and the rents repaired. An uninterrupted recovery took place.

Simple Cyst of the Kidney.—Dr. George E. Brewer presented a patient who was admitted to Roosevelt Hospital with symptoms of intermittent hydronephrosis, having experienced a number of attacks of acute pain in the right lumbar region, extending down along the course of the ureter to the groin. These attacks would be accompanied by swelling and more or less tenderness over the right kidney region. On examination the kidney was easily felt below the ribs, apparently occupying a vertical position with the patient on the back. What appeared to be the round extremity of the upper pole of the kidney could be felt through the anterior abdominal wall. On exposing the kidney by a lumbar incision it was found to be freely movable and lying in its normal position on the quadratus lumborum muscle, and what appeared to be the rounded upper pole proved to be a large translucent thin walled cyst, springing from the anterior surface of the organ, just above the sinus. This was readily enucleated, the raw surfaces drawn together by two catgut sutures, and the kidney anchored in its normal position. She made an uninterrupted recovery.

Double Seminal Vesiculectomy and Vasectomy.—Dr. Brewer presented a negro, 40 years old, who was admitted to Roosevelt Hospital suffering from an abscess of the scrotum, with distinct induration of the epididymis of both sides. On operation the abscess was found to be tuberculous in character, and due to the presence of an extensive tuberculous orchitis of the left side. On further examination it was found that the patient had extensive tuberculous disease of the other testicle, both vasa deferentia and both seminal vesicles. There was no evidence of involvement of the prostate. As the patient had given consent only for the removal of the diseased area in the scrotum, both testicles were removed with only a small area of each vas. The wound healed kindly and he was able to be discharged from the hospital at the end of two weeks. Before leaving he was told the extent of the disease and was advised to return at the end of two weeks for the complete removal of both genital tracts. At the second operation a transverse incision was made in the perineum and the tissues gradually dissected, until the seminal vesicles were exposed. These were much thickened, as well as were the surrounding tissues. With considerable difficulty each was separated from its bed and each vas freed as far upward as the ureter. An incision was then made over each inguinal ring, the canal freely exposed, and the free extremity of each was secured. These were separated from the surrounding tissues of the cord by blunt dissection and the intraabdominal portion liberated by a gradual sawing motion. The structures parted somewhere between the ureteral implantation into the bladder and the brim of the pelvis. Both testicles and vasa were then removed and the wound in the perineum was partly closed and packed with iodoform gauze. The inguinal wounds were completely closed and sterile dressing applied. Practically no reaction followed the operation, and with the exception of a sharp rise of temperature, which followed temporary retention of secretion in the perineal wound, the patient made an uninterrupted recovery. The inguinal wounds were now completely healed and only a small sinus remained in the perineum.

Acute Septic Infarcts of the Kidney.—Dr. Brewer presented a female, aged 26, who was admitted to Roosevelt Hospital November 1 last. Seventeen days before admission she suffered from acute pain in the right flank, radiating to the groin, associated with chills and high fever. The pain continued for several days; she had daily chills and she suffered continuously from fever and general prostration. During the period of her severest pain she would frequently vomit and at other times complain of nausea and anorexia. The physical examination was negative, except for marked tenderness in the costovertebral angle. Leucocytes were 14,000 and there was 70 per cent. polymorphonuclears. The urine contained a trace of albumin and many pus cells. The cystoscopic examination of the bladder gave negative results. The urine from the right kidney contained blood, pus, columnar epithelium, albumin, while the urine from the left contained a faint trace of albumin, very few leucocytes and epithelial cells, and very few red cells. On operation the kidney was somewhat enlarged, surrounded by an edematous fatty capsule, and showed numerous small infarcts and minute abscesses in the cortex. A portion of the kidney substance was removed for patho-

logical examination. The capsule was stripped from the organ and the wound was closed with a small cigarette drain. She made an uninterrupted recovery and had not suffered from renal symptoms since leaving the hospital, and was now in excellent health. The pathologist's report showed it to be multiple abscess in kidney substance.

Report on Renal and Ureteral Surgery, From an Analysis of One Hundred and Forty Operative Cases.—Dr. George E. Brewer read this paper. One of his reasons for selecting this subject was that in looking over his renal histories he found a larger proportion of mistakes in diagnosis recorded than in any other group of operative cases. Three years ago he made a careful analysis of all of his cases and read his report before the Section on Surgery. (See Medical Record, Vol. LXVII., No. 7, February 18, 1905.) Since that time he had had an opportunity of studying additional cases; a review of these and his previous cases he thought might prove of interest. Of the 140 cases there were 48 nephrectomies with two deaths, 48 nephrotomies and exploratory operations with nine deaths, 13 simple decapsulations with two deaths, nine emergency operations on traumatic cases with one death, 15 nephrorrhapies, and nine operations on the lower ureter without mortality. Of the 48 nephrectomies there were six of new growth, seven of tuberculosis, 18 of pyonephrosis, 17 of calculus, three of traumatic rupture, eight of acute septic infarcts, three of hydronephrosis, two cases of ureterovaginal fistula following hysterectomy, one case of pyelonephritis, one of severe hemorrhage following nephrotomy, and one case of necrosis of the organ from a twisted pedicle. Of the 48 nephrotomies and exploratory incisions there were three cases of new growths, six cases of pyonephrosis, 11 cases of calculus, two cases of tuberculosis, 14 cases of septic infarcts, four cases of intermittent hydronephrosis, two cases of pyelonephritis, two cases of polycystic kidney, one case of large cortical abscess, and in five instances the exploratory incision revealed no lesion. While decapsulation was frequently practised in acute septic and other conditions, in connection with other operative procedures, in 13 instances it was the only operation. Of the 13 simple decapsulations, in five patients the double operation was performed for chronic nephritis, in one instance it was performed for a long-standing renal neuralgia of unknown origin, and in two others it was undertaken for the relief of subacute septic infarcts. The 16 nephrorrhaphies were all for the relief of movable kidney. Of the nine operations on traumatic cases, seven revealed evidences of injury to the organ varying from slight capsular rupture to a complete crushing. In two instances a rupture of one or more of the larger branches of the renal vein was present. Of the nine operations on the lower portion of the ureter, in four arrested calculi were found, in two the ureter was kinked by an inflammatory mass, in one there was adherent calcified appendix epiploica of the sigmoid giving rise to an *x*-ray shadow, while in two the ureter was found to be normal. In his first report of 84 cases 12 or 14.2 per cent. proved fatal, while in his last series of 56 cases only 2 or 3.7 per cent. died as a result of operation. Twelve cases of new growth were encountered in this series. Of these three were carcinoma, two hypernephroma, one adenoma, two of solitary cyst, three of polycystic kidney, and in one no accurate diagnosis could be made, although the history suggested a rapidly growing hypernephroma. The group of calculus cases proved an interesting series. In his former report, being impressed with the number of errors in their diagnosis of stone, he made a careful analysis of 36 cases; in 21 cases, or 59 per cent. only, did the operation confirm their diagnosis. And in only 52.6 per cent. of their recent cases of suspected calculus did the operation prove the diagnosis correct. The number of cases which in their onset, symptoms, and subsequent history led them to believe stone to be present in the kidney or ureter were 57. Of these in 32 instances stone was found at operation, in 19 no stone was found, but some other definite lesion which furnished a reasonable cause for the existence of the symptoms, while in six no lesion was found. Dr. Brewer then considered the subjective symptom pain, the objective symptoms, as frequency and painful micturition, vomiting, fever, localized tenderness, and the presence of renal tumor, the results of urinary analysis with reference to hematuria and pyuria, the results of *x*-ray examination, and the results of cystoscopy and ureteral catheterization. From a careful review of these symptoms he said he felt justified in stating that there was no single symptom nor sign, nor any group of symptoms or signs that was absolutely pathognomonic of renal or ureteral calculus, unless the calculus lay in the lower ureter and could be seen or touched by a metal bougie or catheter. The most important factors to be considered in making a diagnosis were pain, tenderness, hematuria, the results of radiography, cystoscopy, and ureteral catheterization. While pain and tenderness were present in practically 100 per cent. of their cases, it should not be forgotten that they were also present in a large percentage of the cases in which no stone was found. Hematuria was present in 45 per cent. of their stone cases, but it was also present in 41 per cent. of the cases without stone. Including all the cases examined, the *x*-ray gave positive evidence of the presence or absence of stone in 79 per cent. of their cases. On five occasions he had observed calculous disease in both kidneys. Of the seven cases of intermittent hydronephrosis, in all there were nonfebrile attacks of violent renal neuralgia. In all the kidney was distinctly palpable. In four instances at operation the renal pelvis was found to be enlarged and relaxed; in three it appeared normal. In four cases in which an enlarged and relaxed pelvis was found at operation only one was cured by the primary operation, and that was an extensive plastic procedure which greatly reduced the size of the pelvis. The other three required secondary nephrectomy. Of the three cases in which no enlargement of the pelvis was noted all were apparently relieved by anchoring the kidney in place. A single case of complete gangrene of the kidney was observed. With regard to acute hematogenous infections in which the lesion was limited to one kidney, there were three important facts regarding the behavior of this form of infection not generally recognized by the profession. The first was that these lesions were often unilateral, the second was that in the severest type of the infection the toxemia was so overwhelming that death occurred before the characteristic renal symptoms were developed, and the third was that these cases in their early symptomatology varied greatly, the clinical picture often suggesting an acute grippe, lobar pneumonia, appendicitis, or cholecystitis. With regard to the treatment the cases should be divided into three distinct groups: 1. The severest type in which nephrectomy was necessary to save life. 2. A milder type, which was often relieved by decapsulation, the opening and draining of the cortical foci. 3. The mildest type, in which no surgical treatment was necessary. The one pathognomonic sign present in all cases was a marked unilateral costovertebral tenderness. In conclusion he briefly recorded his experience in the surgery of the lower ureter.

Demonstration of Instruments.—Dr. Bransford Lewis of St. Louis gave a demonstration of cystoscopes and other instruments.

Dr. Eugene Fuller said that many times in hysterical women one obtained a history of pain somewhere in the abdomen, with perhaps a slight mobility of the kidney, usually the right. He made it a rule never to operate upon these patients unless they gave urinary symptoms. What was said in regard to decapsulation was interesting.

If one took an old afebrile patient with contracted kidneys it seemed to him little could be done by decapsulation, whereas in acute cases much could be done.

Dr. Howard Lilienthal referred to the case of a man who was suddenly taken ill with what seemed to be a grippe pneumonia. Dr. Lilienthal saw him two or three weeks after. There had been numerous consultants and the diagnoses varied. He believed there was intra-abdominal sepsis of some sort and advised immediate operation. An incision was made over the appendix and he found it to be anatomically diseased but not acutely affected. Another incision was made over the gall-bladder, but nothing was found there to account for the trouble. Feeling around he found the right kidney hard as a stone. He turned the patient on the side, upon the flank, and there was disclosed a right kidney covered by a fatty capsule, the hardest he ever saw, of coagulated fat. A nephrectomy was performed and the patient was now almost well. With regard to nephropexy, if a movable kidney was due to trauma, anchoring the kidney at once would relieve the symptoms. It was his practice, whenever a case of supposed chronic appendicitis was brought to the hospital, to have the urine carefully centrifuged for blood cells; if found, he advised the *x*-ray examination. He referred to "crossed pain," *i.e.* pain on one side and the stone on the other; he had seen several such cases. In cases of hydronephrosis he called attention to the fact that the urine would be extremely poor in urinary salts, and the diagnosis could be made by that alone.

Dr. John B. Walker said that he was not in favor of packing gauze in the kidney, but around it, to control hemorrhage.

Dr. Charles H. Peck said he had seen four cases of unilateral septic infarcts during the past year and a half, one being of a moderately severe type. He took it for a case of appendicitis and did a laparotomy. He found a kidney as hard as the one described by Dr. Lilienthal. This patient made a good recovery. The other three cases were all of moderately severe types and while the findings were perfectly positive the renal symptoms subsided without operation.

Dr. Brewer said he had looked for cases of "crossed pain," but had never found such a case. It should be borne in mind that hyperemia from the presence of calculi which gave acute colic was always dangerous. Although it was his practice to go through the cortex of a kidney to extract a stone, he confessed that it might be well to go through the pelvis, in spite of the fact that suturing the pelvis was likely to break down and give leakage. With regard to the control of hemorrhage, he made it a rule when he opened the cortex to simply place a small needle well within the pelvis; he then took a pair of dressing forceps, introduced the points alongside the needle, opened the forceps widely and then placed in his finger. In this way the bleeding was much less. He said he had packed a number of cases, but he never removed the packing before the tenth day. By that time the urine and secretions were so abundant that hemorrhage rarely followed. The possibility of hemorrhage in these cases should always be borne in mind and guarded against. With regard to septic infarcts, he believed the diagnosis could now be made; any case severe enough to warrant operation differed from the symptoms of appendicitis. He never saw an uncomplicated case of the latter with a temperature of 104°. The rise, too, was gradual. In cases of sudden abdominal pain, with rigidity and tenderness over the gall-bladder, with a temperature of 104°, he always thought of the possibility of a septic infarct.

Abscess of Frontal Lobe.—Dr. Fielding L. Taylor reported this case. The patient, 27 years old, was struck with a brick above the right eye in May, 1906, four months before Dr. Taylor saw him. He was not rendered unconscious by the blow and returned to his work the day following. One month later there was considerable inflammation about the wound, which had healed. At the hospital a superficial abscess was opened and several small pieces of brick and some spiculi of bone were removed. He suffered from intense headaches at times, most marked over the occiput. His intellect was sluggish and he could not sleep. His headaches continued, and vomiting was present until September 12, 1906, when he was seen and brought to a sanatorium in this city. He was much emaciated and yawned every few minutes, being very apathetic. The pupils were moderately dilated and reacted well. Vision was diminished. A bilateral optic neuritis was found, more marked on the left. There was slight paresis of the left side of the face without ptosis. The tongue was but partially protruded and deviated slightly to the left. There was distinct weakness of grip in the left hand. Babinsky's sign was not present. The patellar reflexes were absent on both sides. There was incontinence of urine and feces and persistent vomiting. The pulse was 72, respirations 16 and rectal temperature 98° F. During the night the pulse fell to 53. At operation on the day following two ounces of pus were evacuated from a cavity about two inches below the surface in the frontal lobe. The wound was drained with a piece of rubber tubing. A hernia cerebri developed about the size of a hen's egg, but this sloughed off, after which the wound closed. He returned to his home October 17, apparently well, except that he was nearly blind in his left eye and saw poorly with the other. Dr. Taylor heard from him several times during the last year and he stated that he was well, except that his sight was not improving. He made arrangements to come down and be presented before the Surgical Section on November 1, 1907, and was in excellent spirits when he heard from him the latter part of October. He learned that he had died on October 23. He probably had developed a secondary abscess, by the evacuation of which his life might have been saved.

Three Cases of Unilateral Hemorrhagic Nephritis.—Dr. Joseph Wiener reported these cases.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Nevada State Board of Medical Examiners.

Carson City, November 4-5, 1907.

ANATOMY.

1-3. Give function of hyoid bone. From what bones and by what ligaments is it suspended?
4. Which rib is considered the most typical?
5. Bound the astragalus.
6. Name the muscle on the dorsum of the foot.
7. Describe the axillary artery in its origin and termination.
8. How is the inferior vena cava formed, and where does it terminate?
9. Give special names by which the twelve pairs of nerves are generally known.

PHYSIOLOGY.

1. What is the function of the sixth (abducens) nerve?
2. Describe a complete physiological revolution of the heart.
3. Describe the action of the kidneys, and give the normal constituents of urine.
4. Describe the process of segmentation of the ovum.
5. Name the secretions of the alimentary canal, and give the functions of each.
6. What are the functions of the spinal cord?
7. What are amyloid foods? Proteid foods? Give an example of each.
8. What experiments have been made to prove the glycogenic function of the liver?
9. What are the functions of the brain membranes?
10. Describe the phenomena of (a) asphyxia, (b) syncope, (c) sleep.

MATERIA MEDICA AND THERAPEUTICS.

1. What is a decoction; an infusion; a mixture; an emulsion?

2. Give the therapeutic uses of purgatives.
3. Name remedies having a special action upon the kidneys, with indication for and against their use.
4. Name remedies having a special action on heart with indication for and against use.
5. Give the uses of alcohol.
6. Name the various preparations of opium, with dose of each.
7. Indicate condition in which potassium iodide would be useful.
8. What is the dose of veratrum viride? Under what condition can larger dose be used?
9. Indicate the various uses of quinine.
10. Indicate the various uses of iron.

CHEMISTRY AND TOXICOLOGY.

1. Give the physical and chemical qualities of calomel; corrosive sublimate.
2. With what preparations of mercury should the iodides never be combined?
3. Write three prescriptions in which a chemical change takes place.
4. Define difference between mixture and chemical combination.
5. With what are the following drugs incompatible: Iron, mercury, the alkaloids?
6. Name a vegetable poison. Give symptoms of and treatment for poisoning by same.
7. Name a mineral poison. Give symptoms of and treatment for poisoning by same.
8. Describe a case of carbolic acid poisoning. Give treatment for same.
9. What symptoms would indicate over-absorption of carbolic acid from a surgical dressing?
10. Name antidotes for opium, belladonna, digitalis, arsenic, and hemlock.

PATHOLOGY.

1. Give the pathology of acute anterior poliomyelitis.
2. Give the pathology of a chancre of the prepuce.
3. Give the causes of edema.
4. What are the indications of an inflammation?
5. What is thrombosis? How formed?
6. Give the pathology of chronic diffuse nephritis.
7. Give the macroscopical appearance of the lung in the various stages of pneumonia.
8. Give the pathology of cystic ovary.
9. What pathological changes occur during a case of scarlet fever of ordinary severity?
10. Give the pathology of croupous colitis.

BACTERIOLOGY AND HYGIENE.

1. Name and describe the microorganism that produces the plague. Where is it chiefly found?
2. What is a pure culture? How made?
3. How would you diagnose malaria from typhoid fever by the microscope?
4. What is Koch's law?
5. What measures would you take to prevent the spread of tuberculosis?
6. What causes yellow fever? How would you prevent its spread?
7. Suppose a new-born baby were found dead, what would you do to find out whether it was a case of murder or not?
8. Mention four mineral disinfectants, three organic, and three gaseous.
9. What in your opinion should be done in regards to the "social evil" by the municipality or State?
10. Describe the *Bacillus anthracis*.

MEDICINE AND THERAPEUTICS.

1. Give symptoms and parts affected in rachitis.
2. Give stages in pneumonia and treatment of a case from beginning.
3. Where are the lesions in arthritis deformans, and give symptoms?
4. Give causes, symptoms, and pathological anatomy of diabetes mellitus.
5. Give causes, symptoms, and treatment of hemophilia.
6. Make a fever chart of a typical case of typhoid.
7. Give differential diagnoses of gastric catarrh, gastric ulcer, and gastric cancer, and give treatment for gastric ulcer.
8. What are the symptoms of the atrophic form of cirrhosis of the liver?
9. Give symptoms and treatment of pneumothorax.
10. Give differential diagnosis of pericarditis with effusion, and dilatation of heart, and treatment of the pericarditis.

SURGERY.

1. Name the causes of intestinal obstruction.
2. What are the chief surgical diseases of the groin?
3. How are wounds classified?
4. What agents are employed for the production of local anesthesia?
5. What are the causes of secondary hemorrhage?
6. What structures are divided in the operation for strangulated femoral hernia?
7. How are amputations classified in regard to time of operating? What period is most favorable for operation?
8. Describe the operation for ligature of the subclavian artery at its second part.
9. Give symptoms and treatment of section of the median nerve.
10. How would you diagnose and reduce a backward dislocation of the forearm?

GENITOURINARY DISEASES.

1. Give differential diagnoses of simple and specific urethritis.
2. Make a classification of the syphilodermata.
3. Give your treatment of tertiary stage of syphilis.
4. Give different treatments for organic stricture, and give details of each.
5. What is your treatment for hydrocele? Give differential diagnosis.
6. Describe a syphilitic cornea.
7. What are symptoms, causes, and treatment of herpes progenitalis?
8. Give complications of a posterior urethritis.
9. Describe Hutchinson teeth, and what is the cause.
10. What are the symptoms of cowperitis?

OBSTETRICS.

1-2. Give etiology and symptoms of what is generally denominated kidney of pregnancy.
3. What varieties of mellituria may be observed in pregnant women?
4. What organ is most at fault for autointoxication in pregnancy?
5. In what proportion do compound presentations occur in labor?
6. Diagnose a prior pregnancy.
7. Can the sex of the fetus *in utero* be determined?
8. Give etiology and diagnosis of uterine inertia.
9. Give your technique in podalic version.
10. Give absolute indications for cesarean section.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEVADA STATE BOARD OF MEDICAL EXAMINERS.

Carson City, November 4-5, 1907.

ANATOMY.

1-3. The function of the hyoid bone is to support the tongue and to afford attachment to several muscles.
It is suspended from the styloid processes of the temporal bones by the stylohyoid ligaments.
4. The seventh rib is considered the most typical.
5. The astragalus is bounded: Above by the tibia, below by the os calcis, internally by the internal malleolus of the tibia, externally by the external malleolus of the fibula, in front by the scaphoid or navicular.
6. The muscle on the dorsum of the foot is the extensor brevis digitorum.
7. The axillary artery begins at the outer border of the first rib, and ends at the lower border of the tendon of the Teres major muscle; it is continuous with the subclavian artery above, and with the brachial artery below.
8. The inferior vena cava is formed by the junction of the two common iliac veins; it terminates in the lower and back part of the right auricle of the heart.
9. The special names by which the twelve pairs of nerves are generally known are: 1. Olfactory. 2. Optic. 3. Motor oculi. 4. Trochlear or pathetic. 5. Trifacial. 6. Abducens. 7. Facial. 8. Auditory. 9. Glossopharyngeal. 10. Pneumogastric or Vagus. 11. Spinal accessory. 12. Hypoglossal.

PHYSIOLOGY.

1. The sixth (abducens) nerve is the motor nerve to the external rectus muscle of the eye.
3. The normal constituents of the urine are: Water, urea, uric acid, urates, hippuric acid, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen and carbon dioxide.
5. The secretions of the alimentary canal are: Saliva, gastric juice, pancreatic juice, bile, and succus entericus.
The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions

of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) To change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and erepsin, which assist the pancreatic juice in digestion.

6. *The functions of the spinal cord* are: (1) The conduction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

7. *Amyloid foods* are foods containing amyloses or starches. They contain no nitrogen, but are made up of carbon, oxygen, and hydrogen; the hydrogen and oxygen are in the proper proportions to form water. *Example*: Potatoes.

Proteid foods are foods containing proteids. They contain nitrogen, and have a composition similar to that of albumin; other elements contained in them are carbon, hydrogen, oxygen, and sometimes sulphur. *Example*: Meat.

8. *Experiments to prove the glycogenic function of the liver* were made by Claude Bernard. "He fed a dog for seven days with food containing a large quantity of sugar and starch; and, as might be expected, found sugar in both the portal and hepatic blood. But when the dog was fed with meat only, sugar was still found in the blood of the hepatic veins. Repeated experiments gave invariably the same result. No excess of sugar was found in the portal vein under a meat diet, if care was taken to prevent reflux of blood from the hepatic venous system. Bernard found sugar also in the substance of the liver. It thus seemed certain that the liver formed sugar even when, from the absence of saccharine and amyloid matters in the food, none could be brought directly to it from the stomach or intestines. He subsequently found that a liver removed from the body, and from which all sugar had been completely washed away by injecting a stream of water through its blood-vessels, contained sugar in abundance after the lapse of a few hours. This post-mortem production of sugar was a fact which could only be explained on the supposition that the liver contained a substance readily convertible into sugar." (Kirkes' *Physiology.*)

9. *The function of the dura* is protection: Of the *arachnoid*, lymph supply; of the *pia*, blood supply and nutrition.

MATERIA MEDICA AND THERAPEUTICS.

1. *A decoction* is a liquid preparation made by boiling a vegetable substance with water.

An infusion is a liquid preparation made by heating a vegetable substance with hot or cold water; it is not boiled, though boiling water may be used.

A mixture is a liquid preparation, containing one or more insoluble substances in suspension.

An emulsion is a liquid fat in a state of fine and permanent subdivision and suspension in a watery fluid.

2. *The therapeutic uses of purgatives* are: (1) In cases of habitual constipation; (2) to reduce the general blood pressure, for example, in cerebral hemorrhage; (3) to remove the irritant in cases of diarrhea; (4) to aid intestinal antiseptics; (5) to remove toxic products; (6) to remove fluid from the body in various dropsical conditions.

5. "Though decidedly injurious in health, in disease alcohol is a most valuable remedy in appropriate cases. In *vomiting* of yellow fever, seasickness, etc., iced champagne is useful. *Atonic indigestion* of nervous and depressed subjects, cautiously. *Phthisis,* it does good if it promotes digestion and assimilation; otherwise it is very injurious. *Cholera infantum, diarrhea, etc.,* Cognac brandy in full doses. *Cardiac failure,* brandy in small doses repeated as fast as oxidized. *Chloroform anesthesia,* ʒ j-ij of whiskey beforehand, to sustain the heart, and prolong the chloroform narcosis. *Poisoning* by cardiac depressants and snake venom, alcohol freely, to sustain the heart. In *snake poisoning* it is given *ad libitum*. *Diphtheria,* whiskey or brandy in small doses frequently from the commencement, and dilute alcohol sprayed into the throat, is very efficient treatment. *Adynamic fevers,* small doses frequently are often of great value. *Gonorrhea,* Niemeyer is said to have done a lucrative business by treating this affection with injections of tannic acid in port wine. *Insomnia* from cerebral anemia may be prevented by small doses of some alcoholic stimulant at bedtime. *Wounds,* no better dressing than strong alcohol, to prevent putrefaction and protect the surface by coating it with a coagulum of its own albumin. *Bed sores* if threatening, alcohol locally, to harden the tissue. *Cold* from exposure, may be prevented by a moderate dose of alcohol, to restore the balance of the circulation and prevent internal congestion, by relaxing the vessels of the periphery." (Potter's *Materia Medica.*)

6. Pulvis opii, gr. j; extractum opii, gr. ss; pulvis ipecacuanhæ et opii, gr. vij ss; acetum opii, ♏viij; tinctura opii, ♏viij; tinctura opii camphorata, ʒij; tinctura opii deodorata, ♏viij; tinctura ipecacuanhæ et opii, ♏viij; vinum opii, ♏viij.

7. Potassium iodide would be useful in the following conditions: Tertiary syphilis, chronic rheumatism, pleurisy, arteriosclerosis, asthma, mercurial poisoning, chronic inflammations, aneurysms.

8. The dose of veratrum viride is gr. ij; of the tincture, ♏xv. A larger dose can be used in puerperal eclampsia.

CHEMISTRY AND TOXICOLOGY.

1. *Calomel* is a heavy, white powder; amorphous; tasteless and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing; it is incompatible with the mineral acids, with the alkaline chlorides, bromides, and iodides.

Corrosive Sublimate is heavy, white and crystalline; it has a strong, acrid, styptic taste and is soluble in water, in alcohol and in ether; it is decomposed by exposure to light.

3. Three prescriptions in which a chemical change takes place:

℞. Tincturæ ferri chloridi, ♏xxx.
Syrupi simplicis, ʒss.
Tincturæ cinchonæ compositæ, q.s. ad ʒjj.
Misce.; et Signa: One teaspoonful three times a day.

℞. Liquoris ferri et ammonii acetatis, ʒj.
Acidi phosphorici diluti, ʒss.
Syrupi aurantii, q.s. ad ʒiij.
Misce.; et Signa: One teaspoonful three times a day.

℞. Potassii iodidi, ʒiv.
Spiritis ætheris nitrosi, ʒss.
Syrupi simplicis, ʒj.
Aquæ, q.s. ad ʒiij.
Misce. et Signa: One teaspoonful three times a day.

4. *A mixture* is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds. There is no chemical union, and the amounts of the component parts are not definite.

A compound is a substance made up of two or more elements, chemically united with each other in definite proportions.

5. *Iron is incompatible with:* Acids, acid salts, tannic and gallic acids, vegetable astringents, alkalies and their carbonates.

Mercury is incompatible:—The chlorides are incompatible with nearly everything.

Alkaloids are incompatible with: Alkalies, alkaline carbonates, iodine, picric and tannic acids.

6. *A vegetable poison*: Aconite.

"*The symptoms of poisoning by aconite* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of the unabsorbed poison by the stomach tube, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered." (Witthaus' *Essentials of Chemistry.*)

7. *A mineral poison:* Lead.

The symptoms of poisoning by lead are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great pros-

tration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic or by the use of the stomach tube." (Wittbaus' *Essentials of Chemistry.*)

8. *Symptoms in carbolic acid poisoning*: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

Treatment: Emetics, white of egg, stimulants. Alcohol is said to be antidotal.

9. The following symptoms indicate over-absorption of carbolic acid from a surgical dressing: The urine becomes of a smoky or greenish or black color, and is apt to contain albumin; the temperature becomes subnormal, the respirations and pulse feeble; this is followed by muscular weakness and vertigo.

10. The *antidotes for opium* are: Potassium permanganate, or tannic acid, strychnine, and caffeine. *For belladonna:* Morphine or tannin. *For digitalis:* Tannic acid and amyl nitrite. *For arsenic*: Freshly prepared solution of ferric hydroxide. *For hemlock:* Tannic acid.

PATHOLOGY.

3. *The causes of edema:* "Six factors enter into the production of edema, usually more than one acting at a time, viz., positive pressure in the vessels (in proportion as it rises), permeability of the vessel wall, osmosis from excess of salts outside the vessel as seen in the action of a saline laxative, selective action of the endothelium, variations in the blood plasma, and obstructed onflow in the lymph channels." (Thayer's *Pathology.*)

BACTERIOLOGY AND HYGIENE.

1. The microorganism that produces the plague is the *Bacillus pestis.*

It is non-motile, with rounded ends, is about 1½ mikrons in length and a little more than half a mikron in breadth; it stains readily with all the anilin dyes, not by Gram's method; it has no spores, and is not encapsulated.

It is chiefly found in the bubo, spleen, liver, and blood of those suffering from the plague.

2. A *pure culture* is one that contains only one kind of microorganism.

To make a pure culture: "All that is necessary is to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth." (*Reference Handbook of the Medical Sciences.*)

3. In *malaria,* the malarial protozoa would be found, and the Widal test would be negative. The *Bacillus typhosus* of Eberth would not be found.

In *typhoid* the Widal reaction should be positive; there would be no malarial protozoa present. The *Bacillus typhosus* of Eberth might be found in the feces and urine.

4. Koch's law in regard to the bacterial cause of disease is: (1) The microorganism must be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood or secretions of the inoculated animal.

5. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk." (Parkes' *Practical Hygiene.*)

6. Yellow fever is caused by a specific organism not yet isolated. The *Bacillus icteroides* of Sanarelli is supposed by some to be the cause. Whatever the cause, it is conveyed by a mosquito, the *Stegomyia fasciata.*

The spread of yellow fever can be prevented by the use of screens and mosquito nets, by destroying the mosquitoes in the house by the use of burning sulphur or pyrethrum, by draining the swamps, by remaining indoors during the hours when the mosquitoes are most active.

8. *Four mineral disinfectants:* Bichloride of mercury, biniodide of mercury, nitrate of silver, and potassium permanganate.

Three organic disinfectants: Cresol, creolin, and carbolic acid.

Three gaseous disinfectants: Formaldehyde, sulphur dioxide, and chlorine.

10. The *Bacillus anthracis* is a large, rod-shaped microorganism, with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads; it is nonmotile and non-flagellated; it is erobic, and stains by all the alkaline aniline dyes and by Gram's method.

MEDICINE AND THERAPEUTICS.

7. *Chronic gastric catarrh* is generally caused by indiscretions in diet, or by mental worry, it may occur at any time of life, and is characterized by pain in the epigastric region, which generally comes on after eating; there is apt to be morning vomiting, the vomitus consisting of mucus with undigested particles of food; there is seldom hemorrhage; the stomach may be enlarged, and examination of the gastric contents shows free HCl diminished or absent, and the digestive ferments diminished.

Gastric ulcer is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents show an excess of free HCl.

Gastric cancer does not usually occur before forty years of age, is more common in males, pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

Treatment of gastric ulcer: Rest and a light and easily digested diet are absolutely essential. Rectal feeding may be necessary for a time. Sodium bicarbonate, bismuth subnitrate, silver nitrate and opium are the most frequently used drugs. In case of perforation, or when life is threatened by the frequent hemorrhages or when medical treatment is ineffective, a surgical operation should be considered.

10.

PERICARDITIS WITH EFFUSION.	DILATATION OF HEART.
Area of dullness is pear-shaped and the enlargement is chiefly upward.	Area of dullness is not pear-shaped, and the enlargement is chiefly downward.
Dullness may extend to left of apex-beat.	Dullness does not extend to left of apex-beat.
Generally rapid development.	Usually slow development.
Apex beat is feeble or lost.	Apex-beat is generally apparent, and may be powerful.
The heart sounds are not clearly heard.	The heart sounds are generally clearly heard.

Treatment of pericarditis with effusion. Application of small blisters, and the administration of salines and diuretics are indicated. Rest is advisable, also a milk diet. Paracentesis percardii may be necessary.

SURGERY.

1. *The causes of intestinal obstruction* are: Strangulation through apertures, or by means of bands and contracting adhesions; impaction of foreign bodies or feces; the presence of tumors; volvulus or intussusception; intestinal paralysis; disease in the intestinal walls ultimately narrowing the lumen.

2. The chief *surgical diseases of the groin* are: Hernia (inguinal, femoral, and obturator), aneurysms, tumors, abscesses (psoas, glandular, and from hip disease), cysts, ulcers, sinuses, enlarged glands, undescended testicle, prolapsed ovary.

3. *Wounds are classified,* as:

I. Contused and open wounds.

II. Open wounds may be: Incised, lacerated, contused, punctured, gunshot, or poisoned; also penetrating and perforating.

III. Aseptic and septic.

4. *Agents employed for the production of local anesthesia:* Cocain, eucain, stovain, Schleich's solution, ethyl chloride, ether, rhigolene, ice and salt.

5. *The causes of secondary hemorrhage* are: Septic infection, slipping of a ligature, or some other defect of ligation, hemophilia, increased blood pressure due to disease or to reaction from shock, diseased condition of the blood-vessels.

6. *Structures divided in the operation for strangulated femoral hernia* are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous areolar tissue, and peritoneum.

7. Amputations are classified in regard to time of operating, as follows:

(1) Primary, which is performed soon after the accident, as soon as the patient reacts from shock and before there is any fever.

(2) Secondary, which is undertaken some time after the injury, when suppuration or bone or joint disease have supervened.

(3) Intermediate, which is performed during the existence of the fever, but before suppuration or bone or joint disease have appeared.

GENITOURINARY DISEASES.

1. In *simple urethritis* the symptoms are neither so severe nor prolonged as in the gonorrheal variety, pus is not always present, and the gonococcus is never present in the discharge.

In *gonorrheal urethritis* the symptoms are more severe, last longer, and gonococci are always present in the discharge.

2. The following is Cornil's *classification of the syphilodermata:*

1. Erythematous syphilides (roseola).	Diffused; Macular; Papular.
2. Papular syphilides.	Small papules (papular or papulo-granular syphilide); Miliary syphilide; Conical, lichen-like syphilide; Large papules (patches of papulo-lenticular syphilide); Papulo-tuberculous; Papulo-squamous.
3. Vesicular syphilides.	Varicelliform; Eczemiform; Herpetiform.
4. Pustular syphilides.	Acneiform; Impetiginous; Ecthymatous (sometimes superficial and precocious, sometimes late and ulcerated)—ulcerous ecthyma.
5. Bulbous syphilides.	Pemphigus; Rupia.
6. Gummous and tubercular syphilides.	

6 and 9. "The *cornea,* when participating in syphilitic changes, is usually recognized in the victim of inherited disease. There is found, first, slight pericorneal vascularization, in the diffuse form, with one or several centrally situated or marginal opalescent points showing in the cornea. These increase till the whole or a great part of the cornea is involved, producing thus a characteristic opacity limited to the field of the keratitis. With the keratitis of inherited syphilis are often seen the alterations in the color, size, and shape of the permanent incisor teeth, first described by Mr. Jonathan Hutchinson, who regards the permanent upper central incisors as the test-teeth. These are usually vertically and transversely shortened and thinned, with a crescentic notch at the free border, its convexity regarding the root of the tooth. This notching, most conspicuous in childhood, becomes partially obliterated by attrition in later life. The teeth are also often convergent, occasionally separated; in other cases "pegged," and again discolored in shades of a dull brown.

"The punctate form of keratitis is seen both in acquired and in late inherited syphilis. Intracorneal puncta, the size of a pinhead, are then visible, careful observation of which reveals the lack of luster or grayish shade of color of corneal opacities in general." (*Reference Handbook of the Medical Sciences.*)

8. *The complications of a posterior urethritis* may be: Prostatitis, cystitis, pyelitis, epididymitis, inflammation of the vas deferens and of the seminal vesicles, periurethritis, bubo, inflammation of Cowper's glands, peritonitis, gonorrheal rheumatism, gonorrheal conjunctivitis.

10. *The symptoms of Cowperitis* are: Pain, swelling, and a feeling of heaviness and tension in the perineum, all of which are made worse by walking; a small, sensitive tumor can be felt, and there will be considerable constitutional disturbance, such as chill, fever, and malaise; suppuration generally occurs, and dysuria is often present.

OBSTETRICS.

1. *Kidney of pregnancy. Etiology:* Renal insufficiency; renal anemia (due to the pressure of the enlarged gravid uterus on the renal vessels, or to tonic contraction of the renal arteries, which, in turn, is caused by the presence in the blood of toxic matter from the fetal circulation).

Symptoms: Albuminuria (with casts), headaches, vertigo, dullness, lumbar pain, full pulse with increased arterial tension, edema of face and extremities, constipation, tinnitus aurium, nausea, vomiting, and eclampsia.

3. The varieties of mellituria observed in pregnant women are: (1) A physiological glycosuria, and (2) a pathological glycosuria, or true diabetes mellitus.

4. The organ most at fault for the autointoxication of pregnancy is probably the liver, though some observers consider the kidney as chiefly responsible for the condition.

5. Compound presentations occur about once in every 250 cases.

6. The following table (from Dorland) will indicate the diagnosis of a prior pregnancy:

PRIMIPARA.	MULTIPARA.
The fourchet is present.	The fourchet is missing.
The perineum is tense and deep.	The perineum is relaxed and probably torn.
The labia are in apposition.	The vulva is frequently patulous.
The vagina possesses tonicity, and is rough and rugous, with a granular feel.	The vagina is relaxed and smooth.
The cervix is long, soft, and conical; the os is undilated.	The cervix is large, cylindric, short, not so soft, and probably lacerated; the os is patulous.
The abdomen is full, rounded, tense, and resisting to the touch.	The abdominal walls are relaxed and non-resisting to the touch; the skin is loose and wrinkled.
Dark, purplish-red striæ appear late in pregnancy.	The striæ may be both white and livid, the former being present from the beginning of pregnancy.
The breasts are full, firm, and sensitive to pressure.	The breasts are flabby pendulous, and non-sensitive to pressure.
The nipples are usually small and undeveloped or even inverted.	The nipples are large and well developed.
Striæ are absent upon the breast.	Striæ are frequently to be found.

7. The sex of the fetus *in utero* cannot be determined. It can be *guessed at;* a fetal heart beat over 140 is supposed to indicate a girl, below 120 a boy.

10. The *absolute indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	April	6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April	7
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	14
Delaware	J. H. Wilson, Dover	Dover	June	16
Dist. of Col'bia	W. C. Woodward, Washington	Washington	April	14
Florida*	J. D. Fernandez, Jacksonville	Ocala	April	13
Georgia	E. R. Anthony, Griffin	Atlanta	May	—
Idaho	J. L. Conant, Jr., Genessee	Boise	April	7
Illinois	J. A. Egan, Springfield	Chicago	April	15
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May	26
Iowa	Louis A. Thomas, Des Moines	Des Moines	March	—
Kansas	T. E. Raines, Concordia	Topeka	June	9
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	28
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May	21
Maine	Wm. J. Maybury, Saco	Portland	March	17
Maryland	J. McP. Scott, Hagerstown	Baltimore	June	9
Massachusetts*	E. B. Harvey, State House, Boston	Boston	May	12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Detroit	June	9
Minnesota	W. S. Fullerton, St. Paul	St. Paul	April	7
Mississippi	J. F. Hunter, Jackson	Jackson	May	12

* No Reciprocity recognized by these States.
† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Utah reciprocates at present with Colorado, Georgia, Illinois, Indiana, Iowa, Kansas, Maine, Michigan, Minnesota, Missouri, South Carolina, and Wisconsin.

Louisiana.—The State Board will require proof of identification of all applicants for license who are not personally known to some member of the Board.

Iowa reciprocates, under certain conditions, with the following States: Colorado, Georgia, Illinois, Indiana, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Jersey, North Carolina, North Dakota, Ohio, South Carolina, Utah, Virginia, West Virginia, Wisconsin, and Wyoming.

Sprees in the Psychoses and Dementia.—Maurice Ducoste discusses the different sorts of sprees indulged in by different types of mental patients, which he defines as acts of vagabondage without motive. He gives us a résumé of the forms found in various types of mental disease: 1. Alcoholism. Attacks of instability with necessity for movement, and second, attacks in which all memory of the acts performed is absent. 2. Intermittent mania. Maniacal attacks, in which consciousness is preserved, well considered, and recognized by the patient as without motive. 3. Moral insanity. Frequently repeated attacks, conscious, remembered fully, and characterized by a desire to escape their results. 4. Mental debility. Conscience and memory intact, well conducted, but foolish. 5. General paralysis. Early attacks may or may not be absurd, conscience and memory preserved; later in the disease, evidently absurd actions, conscience and memory absent or vague; patient may walk until exhausted without eating or sleeping. 6. Senile dementia. Conscience and memory gone; patient loses himself and cannot get home. 7. Dementia præcox. Attacks of instability, of impulsion, of intellectual failure, and of profound dementia.—*Archives de Neurologie.*

A STUDY OF 400 CASES OF EPITHELIOMA, IN PRIVATE PRACTICE, WITH REMARKS ON TREATMENT AND RESULTS.*

BY L. DUNCAN BULKLEY, A.M., M.D.,

AND

HENRY H. JANEWAY, M.D.,

NEW YORK.

CARCINOMA of the skin exhibits many phases and presents many problems in regard to treatment.

As to its *etiology* we have all to agree that we know but little. We can observe the epithelial degeneration and perverted growth, and note the many local irritating causes which appear to have an etiological significance, but as to the real reason why in most people these irritations will pass off more or less quickly, while in others they will result in a continued misbehavior of the epithelial cells, we are yet in the dark. There has been no lack of earnest and faithful microscopic studies of the diseased parts, and at one time and another there have been rumors and statements in regard to the finding of a cause in some particular microorganism; but competent observers have differed widely concerning the interpretation of what was seen, and it may be stated that thus far no universally accepted etiological element has been proven.

The *diagnosis* of epithelioma is, as a rule, fairly easy to those well acquainted with its manifestations, although one constantly sees cases in which the disease has not been recognized. In a certain number of instances syphilitic lesions have been mistaken for epithelioma, and so they have been cauterized and even excised: and the latter has often been diagnosed as lupus and treated accordingly. In many instances errors occur in the way of not recognizing the epithelial character of the disease, especially in its early stages, and in either neglecting it entirely, or stimulating the mal-growth by unwise superficial cauterizations. In this way trifling lesions are incited to take on malignant action, and often are not properly attended to until they have become almost or wholly beyond remedy. This is especially true in regard to those on the lip and in the buccal cavity; and the many sad instances of advanced epithelioma in these locations which one meets with, which are hopeless or where only the most terrible and destructive surgical procedures can give any hope of relief, and that too often only for a season, are sad to contemplate.

The *prognosis* of epithelioma, therefore, depends very largely upon the wisdom which has been applied to it from the inception of the degenerative process, although in certain rather rare cases the disease appears to be malignant from the beginning, and all attempts to check the progress of the malady seem fruitless. In many instances, however, lesions which are the beginning of epithelioma will yield and disappear entirely with proper, mild, continuous protective and alterative treatment, while in the various stages correct measures will check and remove the difficulty much more effectively than is commonly imagined, as will appear later. There is, therefore, no need for great alarm always, when epithelioma is diagnosed, although there is need of receiving and properly carrying out exactly the best remedial measures before the disease, which always begins as a local process, has gained too great a headway and the lymphatics are invaded. The choice and application of these measures will be considered later, with the results obtained.

The cases which are to be analyzed have occurred in the private practice of one of the writers, and date back some of them over thirty-five years. In all this analysis it is to be remembered that the notes of cases, recorded at the time of each visit, were not made with any view to such a study as this, but only in the ordinary routine of office practice, in order to facilitate the study and treatment of each case. The cases of epithelioma number 417, and occur among a trifle over 15,000 cases of miscellaneous diseases of the skin; the disease thus appearing with a frequency of 2.78 per cent. in this class of practice. The ages and sex are seen in the following table:

TABLE I.

AGES AT WHICH DISEASE BEGAN.

Age	Male	Female	Total
Under 20 years	3	4	7
20 to 25 "	2	2	4
25 " 30 "	3	8	11
30 " 35 "	24	13	37
35 " 40 "	33	16	49
40 " 45 "	32	12	44
45 " 50 "	26	15	41
50 " 55 "	28	18	46
55 " 60 "	27	19	46
60 " 65 "	26	11	37
65 " 70 "	32	10	42
70 " 75 "	18	8	26
75 " 80 "	12	2	14
80 " 85 "	4	3	7
85 " 90 "	..	1	1
90 " 95 "	2	1	3
No age stated	2	..	2
	274	143	417

We observe that the disease appeared much more frequently in males than in females, 274 to 143, or almost two to one. The larger proportion in men is accounted for in part by the number of cases of cancer of the lip, and also on the face, due so often to the irritation of shaving.

A study of the ages is interesting. Carcinoma is known to be a malady largely of adult life, indeed the cutaneous forms of epithelioma are commonly thought to belong to advancing years. We were, therefore, somewhat surprised to observe the relative uniformity of its appearance at each quinquennium between 30 and 70, which is shown in this

*Read before the Medical Society of the State of New York, January 28, 1908.

table; the actually largest number, 49, first occurred between the ages of 35 and 40, and the next largest number, 46, between 50 and 55 and also between 55 and 60. The youngest of our patients was seen at 19 years of age, the oldest 92, when the disease on the nose yielded entirely to mild alterative applications. There were 6 patients in whom the epithelial disease began under 20 years of age. The disease is seen to vary somewhat in the sexes at different periods of life; in advancing years it is more common in males.

The *location* of epithelioma is also an interesting study, and Table II exhibits this in the order of relative frequency.

TABLE II.

Location of Epithelioma.

Location.	*Male*	*Female*	*Total*
Multiple	20	6	26
Nose	77	51	128
Cheek	66	28	94
Lower lip	32	..	32
Forehead	6	13	19
Temple	8	8	16
Eyelid	8	7	15
Tongue	11	2	13
Ear	11	2	13
Neck	7	1	8
Breast	..	8	8
Upper lip	2	5	7
Genitals	3	3	6
Body	3	2	5
Gums	4	..	4
Inside cheek	4	..	4
Inside mouth	1	2	3
Chin	3	..	3
Tonsil	1	1	2
Scalp	..	2	2
Extremities	2	..	2
No location specified	5	2	7
	274	143	417

The most frequent site is seen to be on the nose, where there were 128 cases, 77 males and 51 females. The cheek comes next with 94 cases, 66 males and 28 females, the large proportion in males being due, as mentioned, partly to the irritation of shaving. Epithelioma of the lower lip appears next on the list, of which there were 32 cases, all in males; on the upper lip it occurred in 7 cases, 2 males and 5 females. The disease was observed in other locations with varying frequency, as seen in the table. On the breast were 8 cases, in females, all of the form known as Paget's disease.

Epithelioma has often been thought to appear only in a single patch, but there were 26 cases, 20 males and 6 females, in which there were multiple lesions. In one case, now in the New York Skin and Cancer Hospital, a man aged 40 has epitheliomatous degeneration appearing in about a dozen places about the head; the largest is an ulcerated patch about three inches in diameter behind the right ear, and also one an inch in diameter beneath the left eye.

The *duration* of epithelioma also presents an instructive study. In Table III. is seen the length of time the disease had lasted before the patient came under observation and treatment.

TABLE III.

Duration Before Observation.

Duration unspecified	35
6 months and under	47
6 " to 1 year	19
1 year to 1½ years	22
1½ " " 2 "	7
2 years " 3 "	32
3 " " 4 "	41
4 " " 5 "	31
5 " " 6 "	27
6 years to 7 years	19
7 " " 8 "	16
8 " " 9 "	18
9 " " 10 "	18
10 " " 15 "	42
15 " " 20 "	43
	417

The data in regard to the duration of such a disease as epithelioma cannot, of course, be accepted as wholly accurate, as the table is made up of statements given off-hand, in the ordinary run of office practice; but it indicates to a fair degree the obstinacy of this affection. In some instances the epithelial degeneration had been going on for a longer time than stated, and the trouble was only noticed when some ulceration or crusting had taken place; in others the date had been placed at the time of some abrasion, which being badly handled, had refused to heal and later perhaps had been stimulated into unhealthy action by injudicious application of nitrate of silver.

We see, however, that in a certain number, 47, the trouble had lasted only six months or less, before coming under treatment, while in large numbers of cases it had existed from two to twenty years previous to observation. As will be mentioned later, in these early cases, before the epithelial misgrowth had penetrated into the deeper structures, the tendency to disease was often checked and the tissue restored to a normal condition by relatively mild measures, very carefully and continuously employed; although some of these were radically removed with an arsenical paste, and latterly by the *x*-ray. It is, of course, most desirable that the disease should be definitely recognized and properly treated in this early stage; and the profession should learn to recognize it then and warn patients against neglect or injudicious treatment. But, on the other hand, it is surprising what most excellent results can be obtained in suitable cases by the *x*-rays, properly used, even when the disease has lasted very many years, as will be considered more fully when we come to treatment.

The duration of treatment is a matter which depends upon so many different factors that it is difficult to form any accurate judgment from statistics. It has to do, for instance, with the character, stage, and severity of the disease, the nature of the treatment, the faithfulness of the patient, etc., and it is quite impossible to present data in regard to all these. Table IV., however, exhibits some features of interest:

TABLE IV.

Duration of Treatment.

Cases untreated	45
Duration uncertain or still under treatment	138
Operative cases	38
Cases receiving local treatment, including *x*-ray—	
3 months and under	69
3 " to 6 months	43
6 " " 9 "	13
9 " " 12 "	19
12 " " 2 years	6
2 years and more	46
	417
Duration of *x*-ray cases (included in the above)—	
3 months and under	29
3 " to 6 months	12
6 " " 9 "	4
9 " " 12 "	2
12 " and over	6
	53

In quite a proportion, 138, it is impossible to learn the duration of the treatment, as patients

often left the city with only partial results observed, and owing to change of residence, very many of the letters sent have been returned. There were 38 operative cases, and 247 in which various other treatments were employed. In many operable cases it was quite impossible to secure consent, and only palliative measures were possible; although of late years, by means of proper *x*-ray treatment, combined with various local applications, results have been secured, in many of these cases, such as could never before have been supposed possible. In many of the milder cases a prolonged protective and alterative course of local treatment eventuated in perfect restoration of the part to health. In many of the more severe cases caustics, especially Marsden's arsenical paste, was employed with perfect and lasting results.

The form of variety of epithelioma is a very important feature, and as remarked before, has much to do with the success of the case. Among the cases here analyzed almost every possible form and degree of the disease were noted. In many cases the epithelial disturbance was in its incipient stage, and presented only the earliest departure of the epithelial cells from the normal; indeed, in some of them it would be difficult for an inexperienced eye to decide that the process was one which under adverse influences would develop into a serious epithelioma. In a very large share of the cases the disease was so far advanced that no one with experience could hesitate in regard to the diagnosis. In relatively few of the cases was the diagnosis established by biopsy, but in cases where the microscope was employed the diagnosis was thus confirmed.

(By Dr. Janeway.)—Concerning the varieties of epithelioma, two very distinct kinds of tumors present themselves for consideration. These may be most conveniently named according to Krompecker's classification, namely, (1) Epithelioma basocellare, and (2) Epithelioma spinocellare. These two names refer respectively to the layers of the skin from which the particular variety is supposed to originate.

Whether this assumption as to the explanation of the difference presented by these two kinds of tumors is correct or not, affects very little the fact that the groups which they name are totally different, both clinically and pathologically. The classification is a convenient one, and the term *basalzellen Krebses* is solidly implanted in literature. Pathologically epithelioma basocellare is composed of cells which are more or less fusiform in shape, small in size, and with relatively little protoplasm, but with well formed, generally ovoid nuclei; no epithelioma pearls are present and the cells invade the surrounding tissue in groups. In fact the cells show some approach to a cell of an endothelial type; and some observers have maintained that these tumors are really endotheliomata.

These tumors are, moreover, strikingly different from the ordinary forms of cancer. They represent the small, superficial, slow growths that appear upon the face, nose, ears, and upper lip, and are the tumors which belong essentially to dermatology. Their progress is very slow, and often they will show spontaneous healing; such a case has recently been reported by Dr. H. Jacobsthal.[1] They practically never form metastases. It is this apparent benignity that makes it justifiable to ever resort to any other local treatment than excision. They are peculiarly amenable to *x*-ray treatment, and on account of their slow progress no risk is run by the use of the *x*-ray in this class of growths; on the other hand, it cannot be incorrect to state that, when judiciously used in what may be termed fair cases, 100 per cent. of cures may be expected, and with far less deformity than after excision.

Of a very different character from this group, however, is *epithelioma spinocellulare*. The tumor here is composed of large cells, with a relatively great amount of protoplasm and well formed nuclei; the latter frequently show mitotic figures. The cells distinctly preserve the epithelial type, in form and characteristics, and intercellular union, in the form of prickle cells is present; epithelial pearls, due to the inherent tendency of the cells to preserve the normal life history of a spine cell, are a special feature of these tumors. Metastases are of frequent occurrence, and the growth of these tumors is rapid.

These epitheliomata occur with great regularity in portions of the body not invaded by epithelioma basocellare. They occur upon the mucous membrane of the lower lip, on the tongue, on mucocutaneous junctions, etc.

The most interesting question, of course, is what constitutes the real difference between these two groups of tumors? If, as Krompecker supposes, the epithelioma basocellare originates from the basal layers of the epidermis, one would be led to assume that, as these are the youngest cells, with an *a priori* more potential power of growth and reproductive force, it should produce a more malignant tumor than the more specialized and further evoluted squamous cells of the succeeding layers.

One might also ask, why do the basocellular epitheliomata remain, or appear, so strictly limited to one portion of the body? Why, if their origin is explained by the layer from which they are developed, should they not spring also from the basal cells of other portions of the economy? Certainly this is an interesting question and worthy of some consideration, why do these peculiar growths occur with such preponderating frequency upon a limited area of the body, the face? Certainly, regarding their etiology as distinct from other epitheliomata, the locality must be emphasized as having some important connection.

An explanation may be found in the limiting influence which a tissue more hardened by exposure might have upon a foreign body composed of a malignant new growth. The question of the natural resistance of the tissues themselves to tumor growth, apart from any cytolitic agent existing in the blood plasma, is an interesting one. Ribbert distinctly admits[2] that there is some part played in the production of carcinoma by the surrounding connective tissue, so that when once the epithelial cell, whether by fetal or by post-embryonal glandular formation, or also by dermic inflammatory changes, becomes freed from its normal habitat, the amount of resistance which the connective tissue presents to its independent growth is a factor in the development of a malignant tumor. Further than this, when the process has once started, the independence of the epithelial cells becomes more firmly established, and the resisting power of the surrounding mesoblastic tissue more and more impotent.

Coinciding with this is the established clinical fact that the earlier stages of a new growth are less lawless, less rapid in development, and more local than the later stages; all this shows that we must recognize in the restraining influence of the surrounding tissues a factor in the development or

failure to develop of a malignant new growth. Clinical experience also justifies us in carrying the point a step farther. May we not here recognize a precancerous stage, or perhaps, to express it better, a preliminary stage of cancer? Certainly we have repeatedly observed the healing by bland ointments of ulcers, even on the lower lip, which presented every characteristic of cancer and which either were really cancer, or a preliminary stage of the disease; one feels justified in making this statement because one sees other, exactly similar lesions which, when untreated or maltreated, develop into florid epitheliomata. In the stage of which we are speaking, however, the resistance of the external tissues, when aided by proper protective and alterative measures, is sufficient to enable it ultimately to present an efficient barrier to further epithelial invasion.

This explanation presented by Dr. Janeway seems to account for the very great difference which we continually observe in the behavior of different cases of epithelioma, and the confidence with which one can predict a perfect result in very many of those appearing about the face and head. This is true even when recurrences happen at longer or shorter intervals, for rarely do second manifestations resist any more than those first treated.

It also explains, in a measure, the quite different course of the epithelioma on the mucous mebrane of the lower lip and in the buccal activity. In their very early stages they will sometimes yield to mild and proper alterative applications, but they resent anything which stimulates the surface; and nitrate of silver has been answerable for the steady aggravation of many of them, until they have attained very serious proportions. It also guides us in regard to treatment.

The *treatment* of the cases under consideration has been most varied, for in epithelioma each case is a study, both at the beginning and constantly, until a perfect cicatrix results. Routine treatment of every lesion diagnosed as epithelioma, whether it be by excision, caustics, the *x*-ray, or other means, is to be deplored: and the results seen in many cases which had previously been in the hands of cancer, or *x*-ray quacks, demonstrated the evils consequent upon an ignorant and often vicious handling of the disease.

Excision has been advised in a certain proportion of the cases analyzed, notably those of the lip and mouth, but there are records of only 47 in which it was practised by various surgeons, although there were probably many more. In a good many of these the results, as learned recently, were successful; in a number there was recurrence, and in some instances death ultimately occurred from the disease. The results of surgical interference depend so much upon the stage or condition of the disease, and the completeness of the removal with adjoining glands, that little can be learned from these records. From experience, however, we are firmly convinced that the knife offers still the best, and, indeed, the only chance in a certain class of cases, and when excision is properly and radically done, good results may be looked for in a large proportion of suitable cases, even when far advanced. There were, however, quite a number of instances of enormous development of external cancer which were beyond the hope of operative relief; in some such patients in the New York Skin and Cancer Hospital there has seemed to be much benefit, in late years, from the *x*-ray.

In earlier years many of the cases here analyzed were treated with deeply acting caustics, and especially with the arsenical paste, as employed by Marsden, in the Middelsex Hospital, London. When rightly used, in proper cases, the results of this treatment are excellent, and the scar is all that could be desired; there were thus treated 28 cases, and perfect results known in over 60 per cent., many being lost sight of. This treatment is pretty painful and tedious in the separation of the resulting slough and subsequent healing; it has been little used of late, as the *x*-ray will generally reach just the forms of disease to which this is applicable.

Curettage is often a valuable means of removing the diseased tissue, and, when combined with other proper measures, of curing epithelioma. But to be successful, it must be very thorough, as the chances are very great that some portion of the disease will escape removal and will shortly reproduce new epitheliomatous elements. Hence the curette is rarely if ever trusted to alone, but is followed by the actual cautery or some penetrating caustic. We have had excellent results in many cases by a very thorough curetting, and filling the cavity with powdered pyrogallic acid, with a trifle of cotton packed on top; when the resulting crust fell, in a week or so, all was healed. There were 59 cases in which the curette was used.

The *x*-ray treatment represents the greatest advancement which has been made in the cure of many cases of epithelioma which previously were often most unsatisfactory, and although somewhat of a reaction has set in against the employment of this agent, no one who has carefully observed the results, when properly used, can possibly doubt the wonderful addition which it has made to our armamentarium. We speak advisedly in regard to the cure of epithelioma by this means, for Pusey[3] and others have demonstrated very many cases where the results of even severe cases have been perfect after the lapse of over three years.

The *x*-ray cases amount to 70, some of which are now under treatment, and as we have employed this method only about five years it is too early to draw valuable deduction from them. But no one who watches an epitheliomatous ulcer, which had previously remained and progressed for years, steadily melt away, heal, and finally leave only a very superficial, supple, and often hardly recognizable scar, under this method of treatment, can reasonably question the inestimable value of this agent. In many of these cases the disease was situated about the eye, in the sulcus of the nose, and in places where excision or other active treatment would have wrought havoc with the features, and where we have often seen recurrence after surgical removal.

This is not the occasion to dwell particularly on the technique and mode of using the *x*-ray, which is so often abused; the matter has been so fully considered by others that it is not necessary here. The study of its effects is still in its infancy, and every candid worker will agree that he knows but little as to its real *modus operandi*, and yet that he knows more of its actual effects, and how to secure them best, with each application made. It is, indeed a two-edged weapon, which may harm both patient and physician, but when rightly managed it need not harm either, and can wonderfully benefit the former.

Great claims have been made for radium in the treatment of certain forms of epithelioma. It was used for quite a while in our service at the New York Skin and Cancer Hospital, but we could not see that it produced as good results as the *x*-ray, and no satisfactory data can be given.

It would be useless to detail the many modifica-

tions of local treatment which have been employed in individual cases during the past 35 years, with varying success, for experience has gradually narrowed down the methods of treatment to the four mentioned, namely: 1, Complete and radical surgical removal in certain cases where this seems imperative; 2, very thorough and deep cauterization, preferably with Marsden's arsenical paste, used as he describes; 3, the curette, employed as previously explained; and 4, the *x*-ray. To these may be only added that in the earliest, superficial epithelial derangement, really the precancerous stage, the constant application of ointments, containing such substances as salicylic acid, pyrogallic acid, ichthyol, etc., will often succeed in restoring to health lesions which, if untreated or maltreated, will unquestionably result in active epithelioma.

In conclusion, therefore, we wish to emphasize the following points:

1. The most frequent form of cancer which the dermatologist is called on to treat is, both pathologically and clinically, quite a different growth in its relatively benign course, from the usual conception of cancer.

2. It occurs chiefly about the face, in places where radical operative measures are apt to produce serious deformities, which very materially add to the patient's discomfort.

3. While the experience of 35 years demonstrates that many cases can be permanently cured by caustic pastes, these are at times disappointing and may lead to an aggravation of the trouble.

4. The curette cannot be depended on alone, but requires additional destructive agents to the base left after operation.

5. By the proper use of the *x*-ray we have a safe, and, in cases that have not been grossly neglected or maltreated, a sure method of cure, with the least amount of deformity.

6. In cases where knowledge and experience shows that these lighter measures are not likely to avail in checking the course of the disease, recourse should certainly be made to complete surgical removal, as this has been shown to be permanently successful in a reasonable proportion of cases.

ACUTE INVASION OF THE KIDNEYS BY THE BACILLUS COLI.*

By W. HANNA THOMSON, M.D.,

NEW YORK.

The pathology of derangements of the kidneys abounds with uncertainties and unsettled problems because of the many yet unknown factors in the physiology of these paradoxical organs. Thus, as the proper tissue of a secreting gland is constructed for elaborating its own specific secretion, it is natural to suppose that the more that tissue is destroyed the less would the gland secrete. But if three-fourths of both kidneys be experimentally excised, the remaining one-fourth will secrete much more urine, and a great deal more urea, than will the intact kidneys, and the animal will die from his normal renal secretion being so excessive. This fact well illustrates how little we know of the processes of bodily metabolism.

Likewise, the clinical accompaniments of the different diseases of the kidneys which we meet in practice are more contradictory in their significance than those of any other class of affections, except in Graves' disease. A typical case of parenchymatous nephritis ends in uremia, but so does a chronic interstitial nephritis. The antecedents of the first are abundant albuminuria and general anasarca; those of the other are virtually no albuminuria and no dropsy. An acute nephritis may end in suppression of urine and death from uremia. But the most complete suppression of all is by sudden obstruction of the ureters by renal calculi. Here the patient dies without either the symptoms or the accompaniments of uremia.

The subject being so extensive, I must now limit myself to only one condition of renal derangement—and that also will be found to be no exception to the rule—that the kidneys are fertile in surprises for the medical man. That condition is acute septic invasion of the kidneys by the *Bacillus coli*.

The commonest occasion of this condition, as might be expected, is in the course of typhoid fever. The state of the intestinal walls in this complaint affords many opportunities for the entrance of this organism into the general circulation. The rule, however, is for this complication to occur only in the later stages of the fever. Sometimes its advent then is marked by severe rigors, the occurrence of which in the course of typhoid fever should always raise suspicions of this invasion of the kidneys and lead to immediate examination of the urine for the presence of this bacillus. During the rigors the aspect of the patient is very serious, as if he were on the verge of fatal collapse. If the patient, however, is young, the prognosis is not necessarily bad; it is otherwise if advanced in years, particularly if fleshy and the rigors are of frequent occurrence. At other times, without rigors, the patient's general symptoms become very unfavorable. If he has not had delirium before, it now sets in. The temperature also becomes very irregular. Suspicion of the invasion of the kidneys by this bacillus should be at once aroused if the urine diminishes. All this was well illustrated in the case of a medical friend with typhoid fever whom I saw in consultation. In the fourth week of apparent beginning convalescence he suddenly became delirious, with a marked rise of temperature. The urine also was much decreased. I recommended his physician to have his urine examined for the *Bacillus coli;* they were found in myriads in his urine. Under specific treatment he at once improved, became rational, the temperature fell, and the bacilli disappeared from the urine. A week afterwards he had a relapse, with a reappearance of the bacilli, and under the same treatment again improved. Ten days afterward, when his temperature had become normal, he suddenly developed pulmonary edema, to which he succumbed in a few hours.

Another example, and wholly different in its antecedents, is when the invasion supervenes in a patient who has chronic interstitial nephritis. As often is the case in this condition, the patients may have been but little discommoded by their kidney disease and have attended steadily to business. Suddenly, and usually after some indiscretion of diet, they have an attack of gastroenteritis. The kidneys at once show a tendency towards suppression, and if the actual condition is not recognized, so as to be specifically treated, the patients soon succumb. I al-

*Paper read at the New York Urological Society, January 22, 1908.

ways dread an attack of so-called cholera morbus in elderly people, and recommend that the state of the kidneys should be immediately investigated.

At other times these patients are suddenly taken with serious cerebral symptoms, passing into coma, with hyperpyrexia. Such fever accompanied by oliguria is very significant, as a brief account of the following case will illustrate. I was called in consultation to see a lady whose physician told me that she had showed some symptoms of renal trouble for a good while, but after partaking of a too full and varied meal she complained of her head, high fever set in, and she soon passed into deep coma, with a temperature of 105°. I gave a favorable prognosis, and, by active treatment, in twenty-four hours the whole clinical picture changed, and in a week she was out of bed.

At other times this invasion occurs in patients who have had chronic ulcerative colitis, and, owing to its illustration of the specific nature of this condition, I would give the following example: I was called to see an old friend of mine, a physician in large practice, and who had often before called me in consultation, but now had been wholly delirious for six weeks. I was told that he was succumbing to a severe attack of acute parenchymatous nephritis, in corroboration of which statement I was shown copies of frequently repeated examinations of his urine by the chief of one of the best equipped laboratories which we have in this city. At the bottom of each page the diagnosis was written "severe acute parenchymatous nephritis, with much albumin, blood, and casts." On examining the patient I said that, whatever the laboratory diagnosis might be, he did not show a single clinical symptom of acute parenchymatous nephritis. As the patient had more than once consulted me previously for ulcerative colitis, I suspected that his was a case of septic invasion of the kidneys by the *Bacillus coli,* and therefore gave a very favorable prognosis. His physicians could hardly agree with me, but agreed to put him upon the treatment I recommended. The reasons for my diagnosis were, in the first place, that he had not a sign of edema, that his pulse was compressible, and, moreover, that delirium—certainly the long, active delirium he had shown—was rare in parenchymatous nephritis; and if I had suspected that that was the condition I would not have given such a favorable prognosis. Thirty-six hours after the treatment had been begun the comment written at the bottom of the report coming from the laboratory was, "astonishing improvement," "no albumin, no blood, and no casts!" On my first requesting that his urine should be examined for the *Bacillus coli* the report was that they were found in exceptional abundance. A little over a year afterwards my friend, this patient, called upon me, and said he had never felt better in his life and that he was busy at his profession for sixteen hours a day.

I once had a similar development occur in the case of a very severe and prolonged attack of influenza, also in the case of a well-known medical man. When we recall that in the first year of this epidemic (in 1890) in New York we had so many cases of fatal gastritis or of gastroenteritis occur in influenza, this infection doubtless occasionally allows of such an invasion. This patient, after a number of weeks of really prostrating developments of the infection, began rather suddenly to show cerebral symptoms, with diminished urine. I at once had his urine examined for the bacillus and it was found in great numbers. A short course of treatment entirely altered the symptoms for the better.

I do not know of any serious condition in which so much can be done if its nature is only recognized, nor, I may add, in which the event is so generally fatal if not specifically treated. In each case, however, the diagnosis can be certainly made only by the examination of the urine specially for the *Bacillus coli* and then finding them in great numbers. As the urine is an unfavorable medium for the growth of this organism, the inference is plain that they could not have entered the bladder except by way of the kidneys, because no accidental introduction of them by catheterization or otherwise could account for the immense numbers of these bacilli usually found in such cases. The clinical symptoms of this condition are unlike those of any other kidney derangement. I have not met with a single case of convulsions, but active delirium is common. There is no edema and the pulse is soft. Profound coma soon supervenes in all cases, with hyperpyrexia, and at autopsies the kidneys are then found riddled with discrete collections of the *Bacillus coli.* The specific treatment above alluded to I would briefly outline as follows:

First, a dose of calomel, 10 grains, and compound jalap powder, 40 grains. If the patient is so comatose that swallowing is impracticable, no time should be lost in resorting to the specific medication being administered per rectum, and which is 10 grains of urotropin and 10 grains of sodium benzoate in 4 ounces of water, given in urgent cases every two hours. When the symptoms improve, the doses may be administered by mouth every three or four hours. When it is otherwise allowable, the action of the mercurial purgative may be awaited before beginning with the urotropin. The urotropin is specific in its operation because it is an active poison to the *Bacillus coli,* and, as it is excreted by the kidneys, it promptly destroys this invading organism. Urotropin alone, however, often irritates the kidneys and urinary passages, with symptoms of strangury, but in my experience such an occurrence rarely happens if sodium benzoate is given with it. For the rest, the calomel purgative should be repeated every other night until the kidneys are secreting freely. Meanwhile great assistance will be furnished against the oliguria by frequent enteroclysis with hot normal saline solution at 120° F., or, if that is not sufficient, with hypodermoclysis.

In conclusion I would remark that for progress in medicine, clinical observation and laboratory research are analogous to our two legs in walking. Some of us seem to choose one of these two legs chiefly or alone to go by, and in justification they point out how halting the gait is when their favorite leg is not used. In one of the cases above reported I disagreed with the laboratory diagnosis because the clinical symptoms told a different story. But both my diagnosis of this serious kidney derangement and my line of treatment for it are based on a paper published ten years ago by our distinguished fellow-townsman, Dr. Simon Flexner, on septic invasion of the kidneys by the *Bacillus coli* in those cases of chronic interstitial nephritis which often terminate so unexpectedly with symptoms of acute nephritis, and which he showed to be due to recent, and not to chronic, affection of the kidneys by this organism.

On the other hand, I regard it almost certain that not a few cases of chronic kidney disease are primarily due to repeated slight infections proceeding from the intestinal tract. However that may be, no clinician should fail to watch that he is always keeping step with the research laboratory.

ARNETH'S METHOD IN THE CLINICAL STUDY OF PULMONARY TUBERCULOSIS.

By G. E. BUSHNELL, Surgeon U. S. Army,
AND
C. A. TREUHOLTZ, Contract Surgeon, U. S. Army,
U. S. ARMY GENERAL HOSPITAL, FORT BAYARD, NEW MEXICO.

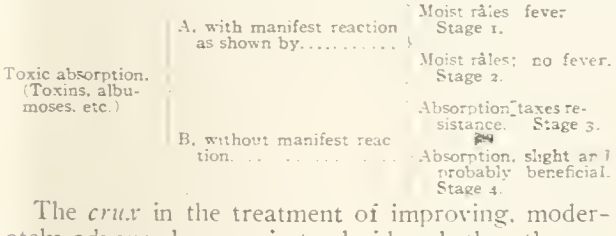
In his study of the relation of the neutrophilic leucocytes to infectious disease, Arneth assumes that these leucocytes enter the circulation with an undivided nucleus, and that the cells as they grow older are characterized progressively by an increasing number of nuclear subdivisions and by a fuller development of the granules. The condition of the neutrophiles in a given case is determined by a comparison of the percentages of cells with one, two, or more nuclear subdivisions with the normal percentages obtained by averaging the counts of a number of healthy individuals. If it is found that the neutrophiles consist of cells with single or few nuclei in a percentage relatively large as compared with the normal blood, he infers that the older cells have been destroyed in some way, probably as a result of contact with bacteria and bacterial toxins and their places supplied by young cells which have not yet completed their development. Increased activity in the production of leucocytes is a manifestation of the reaction of the organism to bacterial infection. In cases with good reaction, a leucocytosis is present. In less favorable cases the production of new leucocytes keeps pace with their destruction, and the leucocyte count is normal. When reaction fails, a leucopenia is present. The loss of the older neutrophiles furnishes an indication as to the amount of circulating bacteria and bacterial toxins.

This theory seems to throw much needed light upon the relations of leucocytosis to infection, but lack of space forbids any attempt at a discussion of the many interesting questions thus raised. The study which it is the object of this paper to report was purely clinical in its scope, undertaken with a view to determine whether Arneth's method might be of practical assistance in the treatment of pulmonary tuberculosis. For the details of the method, the reader is referred to the original monographs[1], [2], [3], of Arneth and to a paper by Arnold C. Klebs and H. Klebs, first read in the 1906 meeting of the National Association for the Study and Prevention of Tuberculosis, and published at a later time in the *American Journal of the Medical Sciences*.[4] For an understanding of the following it need only be stated that Arneth divides the neutrophiles into five classes according to the number of nuclear subdivisions, the fifth class comprising leucocytes which have five or more subdivisions. He further subdivides each class according to the shape of the nuclear fragments, distinguishing myelocytes, slightly indented and deeply indented nuclei in the first class, and classifying the fragments of the succeeding classes as circles (*runde Kerntheile* and loops (*Schlingen*). The classes being arranged from left to right in numerical order when tabulated, an increase in the percentage of cells with few nuclei is conveniently denominated the "drift to the left."

The subdivision of classes is practised by Arneth on the assumption that the nuclear subdivisions which are loop-shaped, that is, are longer than broad, are destined to subdivide still farther, whereas the approximately circular (spherical) subdivisions have completed their development. If therefore, there be found, for example, a preponderance of cells with two circles in Class Two, the count is not so favorable, other things being equal, as if the majority of the cells contained two loops. In our counts the shape of the nuclear fragments is always observed and recorded. It is doubtful, however, whether such distinctions are of practical importance, and they will be ignored in this paper.

Arneth uses Ehrlich's triacid stain. He gives the impression that he prefers a stain which does not stain the nucleus sharply in order that the threads connecting its subdivisions may not become visible. We prefer a sharp nuclear stain and count portions of the nuclei connected only by a thread as separate nuclei. After some experimentation we always use well-ripened Delafield's hematoxylin and a five-tenths per cent. alcoholic solution of eosin, staining first with eosin and washing before applying the hematoxylin. In properly stained specimens the protoplasm of transitional cells and large lymphocytes is grayish blue: that of the polymorphonuclears light pink. Comparative counts of the same blood stained by hematoxylin and eosin and by Hasting's stain give practically the same percentage of the transitional cells and a difference of four per cent. in the large lymphocytes. The advantage of the hematoxylin stain is that it does not stain the granules, which if well stained obscure the nucleus and render the counting of its division difficult: also, that if the nuclear threads are well stained they call attention to divisions of the nucleus which might otherwise be counted as one. The blood smears must be thin. It is our invariable practice to count two hundred cells.

In a case in which the patient has no fever and no moisture in the lungs, the important question to decide with reference to treatment is the amount of toxic absorption which still continues. Too often it is assumed that the absence of manifest signs of reaction as obtained by the thermometer and stethoscope is a proof of complete arrest of the morbid process. Yet all will admit that in a well-marked case of tuberculosis of the lungs tubercle is still present, toxic absorption is probably still active, and the normal temperature and improved pulmonary conditions mark but the first steps toward a permanent cure. The stages which must be passed through as the patient improves in such a case may be represented schematically as follows:



Toxic absorption. (Toxins, albumoses, etc.)
A, with manifest reaction as shown by.....
Moist râles fever Stage 1.
Moist râles; no fever. Stage 2.
B, without manifest reaction.
Absorption taxes resistance. Stage 3.
Absorption, slight and probably beneficial. Stage 4.

The *crux* in the treatment of improving, moderately advanced cases, is to decide whether the patient who has passed through Stages 1 and 2, has reached Stage 4, or is still in Stage 3. When the tuberculous lesion is large, the wise man gives the patient the benefit of the doubt and keeps him quiet. It is hard, however, to exact obedience indefinitely in the absence of any means of demonstrating the correctness of one's opinion, and some cases of disseminated tubercle are very deceptive in their simulation of health restored. An objective proof that toxic absorption is present in a degree which constitutes a tax upon the resistance of the afebrile patient is one of the great desiderata in the treatment of pulmonary tuberculosis. Arneth has, it appears to us, furnished the means of securing such proof in his method of studying the neutrophilic leucocytes.

Arneth has shown that the intravenous injection of nuclein, peptone, tuberculin, and tubercle bacilli causes a marked drift to the left in the healthy rabbit. Relatively large doses of tuberculin produced the same results at his hands in the tuberculous human subject. It seems certain, therefore, that bacterial toxins can influence the leucocytes. In acute infections the influence is so marked that there can be no reasonable doubt that it is due at least in large measure to the toxins of the disease. If, however, we apply the method to measure toxic absorption in the afebrile apparently convalescent patient, it may not be out of place to inquire upon what grounds we consider that the count of the leucocytes is a trustworthy indication of such absorption. Our confidence in the method is based upon the fact that in many observations we have met with no case in which the count was a "wild" count, at variance with the subsequent course of the disease or the otherwise ascertained data as to the patient's condition. It bears on the other hand no relation to the state of the general nutrition. Fat and to outward appearance healthy patients with large lesions give bad counts; thin and pale subjects without tuberculosis may give normal or even hypernormal counts. Exercise and the ingestion of various drugs affect to a slight extent the leucocyte-picture even in the healthy. The intravenous injection of nuclein, peptone, etc., above referred to, has a powerful but very transitory effect in the healthy animal. It may, therefore, be easily seen that the blood of patients who exercise irregularly and to relative excess may furnish counts which fluctuate widely because absorption varies. For trustworthy results it is necessary that patients lead well-regulated lives and that important complications, especially intercurrent infections, be carefully excluded. Arneth lays stress upon the relatively marked effect of pyogenic organisms upon the leucocytes and is inclined to ascribe the bad count in advanced cases of tuberculosis to infection by these bacteria (mixed infection), and to the draining away of leucocytes in purulent expectoration. We shall, however, cite two severe cases, one of them having a large cavity, in which the Arneth count is bad although expectoration has always been scanty and cultures of the sputum seem to exclude mixed infection. From the study of these cases as well as of the many afebrile cases in which also mixed infection is improbable, there seems to us sufficient evidence that the toxins of tubercle directly and strongly influence the leucocytes.

In advanced and active tuberculosis, the method of Arneth gives us, as a rule, no information which we do not already possess. The leucocyte counts fluctuate but are always abnormal. In cases admitted to this hospital, usually after a long railroad journey, immediate examination of leucocytes, in all but slight cases, gives unfavorable counts which are much improved as a rule after the patient has rested a week or more. Absence of improvement after such a period of rest is of very evil prognosis, but it by no means follows that the prognosis is necessarily good for patients who thus improve, the improvement in advanced cases being too often temporary.

In studying Arneth's tables one feels a sense of confusion from the large number of subdivisions. A portion of the difficulty is done away with by neglecting the distinction upon which Arneth insists as to the shape of the nuclear fragments in the various classes. It still, however, remains difficult to decide at a glance how a count is to be classified and the examination and comparison of a large number of counts is a tedious matter. An attempt has been made by us to obviate this objection by the use of an arbitrary index which is made by adding together the percentages of Class 1 and Class 2 and one-half the percentages of Class 3, thus, as it were, taking the number of neutrophiles which are to the left of a line drawn through the middle of the table. For a rough estimation the point of chief importance is the relative percentages of Class 2 and Class 3. For example, the count of a patient on admission was 17:57:23:2:1; index 85.5. Nine months later it was 6:23:50:21:0; index 54, the difference between indices being largely due to transposition of percentages of Class 2 and Class 3. In this method, therefore, Class 2 is fully represented while the number of Class 3 is given but half its value. Class 1, which generally contains a small percentage, is merged in Class 2 without materially affecting the result, and Class 4 and Class 5, the percentages of which are practically deducted in this method, are likewise not distinguished. For severe cases in which Class 1 has a high percentage the index gives relatively too favorable figures. The chief utility of the Arneth method is, however, considered to be found in the study of cases which are approaching a cure and in such cases this objection is of no practical importance. A manifest advantage in the use of an index is that it permits the construction of a curve. The index of Arneth's average count of normal individuals is 60.5; of our normal average, 67.

The number of cases observed by us is not sufficient to justify dogmatic statements. The study of the relations of the Arneth's index to the clinical course of pulmonary tuberculosis leads us to the following provisional conclusions:

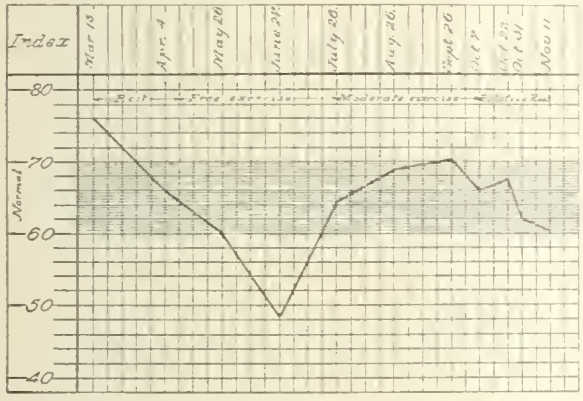
The index of the normal individual at work is between 60 and 70; with complete rest and abundant food, the index should fall below 60. A tuberculous patient can not, therefore, be considered as entirely free from manifest toxic absorption if his index remains above 60 when at rest. Practically, however, patients with an index between 60 and 70 may usually be allowed moderate exercise. If the index remains below 60, with moderate exercise, the case is very favorable. Some tuberculous cases work for years with an index above 70. Usually in such cases some activity persists or a small suppurating cavity is present. In general, however, an index of 70 or more is an indication for absolute or relative rest. Certainly no patient can be considered cured whose index is found to be usually above 70. Too favorable conclusions must not be drawn from an occasional fall in the Arneth index, nor must too great importance be ascribed to minor variations.

The following cases will serve as illustrations of the practical applications of the Arneth method:

Case I. The patient was admitted March 8, 1906, with tuberculous laryngitis. There was considerable inflammatory thickening of the left ventricular band and cord and a small swelling near the right arytenoid. No ulceration was visible. An apparently inactive lesion, presumably tuberculous, was found at the apex of the right lung. Tubercle bacilli present in sputum. Temperature, slightly raised. Arneth count, index 76. The presence of tubercle bacilli in connection with the somewhat unfavorable "blood-picture" raised the question whether some ulceration might not be present at a point invisible with the laryngoscope or whether the lung lesion was as inactive as it seemed. Such doubts were soon set at rest by the future course of

the case and the rapid improvement of the Arneth count was an important factor in determining the prognosis. Observations by the Arneth method having been taken at nearly regular intervals, the subjoined chart was made to show the curve of the indices, which were as follows: March 15, 1906, 76; April 24, 66; May 26, 60; June 27, 48.5; July 29, 64.5; August 26, 69; September 26, 76.5; October 7, 66; October 22, 67.5; October 31, 62; November 11, 60.5. During the first four months, the patient was taking but little exercise. The rapid fall reaching a hypernormal blood-picture in four months, showed pretty conclusively the absence of any considerable activity of the tuberculous process. After this result was reached, the patient began to ride and drive and the subsequent fluctuations, remaining close to normal, are about what might be expected in the healthy man under the same conditions as respects exercise.

The patient left the hospital on November 4, 1906, and plunged into active work in the East. He was seen in May, 1907, when on laryngoscopic examination the left cord was found to be apparently normal, except for a slight trace of hyperemia, and a depression near the right arytenoid marked the site of the former swelling. The patient has since remained well.



Case II. The patient, a large and stout man, after treatment for six months had gained so enormously in flesh and felt so well that he desired to go to duty. Some activity was, however, still found present in December, 1906, and the Arneth count was, December 2, 1906, 9:41:42:7:1. I. 71. In February, 1907, the disease seemed arrested. The Arneth count on February 5, 1907, was 6:29:50:15:0. I. 60. The patient was returned to duty, and has since, it is believed, remained well.

Case III. A soldier, admitted to this hospital, November 15, 1899, with a small tuberculous lesion of the upper lobe, right lung. Has been on duty as a clerk since March, 1900, and not under close medical supervision. An athletic man of vigorous physique, devoted to violent exercise. In 1905, the lesion in the right lung had healed, but a small active lesion was detected in the left upper lobe. His case is typical of the class of patients in apparently excellent health with always normal temperature in whose lungs small foci of tuberculous activity nevertheless persist indefinitely, it is believed, because they do not allow themselves sufficient rest. The neutrophile counts are too widely separated to be of much significance so far as the clinical course of the case is concerned, but it is interesting to note that even so small lesions in so vigorous a patient exert at times a perceptible influence upon the leucocytes. At present his disease appears to be quiescent.

Arneth counts:

October 16, 1905,	8	55	32	5	0	I. 79
February 5, 1906,	5	42	49	6	0	I. 69.5
March 7, 1907,	5	40	42	7	0	I. 72
December 13, 1907,	6	44	34	16	0	I. 67

Case IV. Patient, a robust man, was originally admitted in 1903 with a small tuberculous lesion of the upper lobe, right lung. Returned to his home in July, 1904, apparently cured. Not feeling well in the following spring, he started again for the West. Had a severe hemorrhage on the train and arrived at this hospital on a cot, May 6, 1905. Diagnosis, disseminated tubercles, upper, middle and upper part lower lobe, right lung. During treatment temperature was usually normal or subnormal. The patient was in good flesh and to outward appearance in good health. Lesions pursued a sluggish course.

Arneth counts:

November 10, 1905,	9	30	40	6	0	I. 71
January 10, 1906,	4	42	44	9	1	I. 68

The patient left this hospital, March 31, 1906, and engaged in business pursuits. At this time his lesions seemed inactive. He returned for a brief visit on August 24, 1906. On physical examination the condition of the lungs was found unchanged. Arneth count, August 28, 1906, 13:53:31:9:0. I 81.5. Notwithstanding the large lesions, the patient's condition during relative rest seemed to approach closely to the normal. This last count in which the rise of the index is probably due to the increased absorption of toxins from the exertion attendant upon travel, shows how unstable the condition of such a patient really is.

Case V. A negro soldier who had only doubtful indications of pulmonary tuberculosis and negative sputum during a treatment of six months, on February 18, 1907, had an Arneth count: 3:25:54:17:1. I. 55. He was returned to duty on April 23, 1907, but was readmitted on September 3, 1907, with an extensive tuberculous involvement of the lungs. On November 6, 1907, Arneth count was, 30:56:14:0:0. I. 93. Death occurred on December 24, 1907. In the lungs were found at the autopsy two small cavities with thick walls and deeply situated tubercles becoming fibrous, also an enormous number of recent tubercles. It seems altogether probable that the tuberculous disease was arrested at the time of the count of February 18, and that under the less favorable conditions of military service a reinfection from the old lesion or from without took place subsequently.

Case VI. In the following case the persistently unfavorable Arneth count predicted a more serious ending than was anticipated. The patient, a powerfully built and corpulent man, was first admitted to this hospital in 1899, and underwent several prolonged periods of treatment. He had well-marked tuberculous involvement of the upper lobe, left lung, and a lesser involvement of right upper lobe, besides tuberculosis of the prostate, spermatic cord, and epididymis. For the latter complications several surgical operations were performed at intervals.

In the spring of 1907 he sought infirmary treatment with complete rest in the hope of recovering more rapidly. At this time the lung lesions did not manifest much activity, the sinuses remaining from the operations on the spermatic cord were closed. Expectoration, rather profuse: purulent. Temperature, usually nearly normal. Nutrition, very good. The chief unfavorable signs were the persistent rapidity of the heart action and a slight bluish tinge in the ruddy color of the face. Asthmatic attacks occurred at night occasionally. There were

considerable fluctuations of the temperature during the summer. On November 3, 1907, the temperature shot up and two days later hemoptyses occurred. The hemorrhages were numerous and profuse for several days. The expectoration gradually assumed a prune-juice color, pulmonary edema developed, and the patient died on November 12. The autopsy showed a slightly dilated and markedly fatty heart. In the left upper lobe a large cavity with unusually thick and dense fibrous walls: tubercles in both lungs undergoing transformation into fibrous nodules; tubercles in the prostate, calcified; degeneration of kidneys and liver.

In short, the patient was becoming cured of his tuberculosis when he died of secondary degenerations and infections. In the light of the autopsy it seems probable that in this case the unfavorable counts are largely to be ascribed to secondary infection and to the chronic suppuration of the cavity with the consequent loss of leucocytes.

Arneth counts:

October	15, 1905,	12 : 54 : 28 : 6 : 0. I. 80
February	6, 1906,	11 : 62 : 27 : 0 : 0. I. 86.5
July	26, 1906,	14 : 52 : 30 : 4 : 0. I. 81
March	23, 1907,	9 : 52 : 33 : 6 : 0. I. 77.5
April	27, 1907,	16 : 66 : 18 : 0 : 0. I. 91
June	10, 1907,	10 : 61 : 23 : 6 : 0. I. 82.5
July	31, 1907,	29 : 58 : 11 : 2 : 0. I 92.5

That other causes than mixed infection and chronic suppuration can produce similar results is shown by the two following cases:

Case VII. The patient was admitted on June 3, 1905, with high fever, consolidation, and breaking down of the greater part of the right lung. He remained absolutely confined to his bed for more than two years. An enormous cavity developed with consequently marked displacement of the heart. His present condition is very good, activity of the tuberculous process having nearly disappeared, and the temperature having become almost normal. During his entire illness there has been no expectoration further than a drachm or two of thin mucopurulent fluid in the morning. In a recent bacteriological examination of the sputum it was washed six times in sterile water, the last water remaining sterile. On plating, each of two Petri dishes developed but one colony, of streptococcus and staphylococcus respectively.

Arneth counts:

August	24, 1906,	26 : 47 : 27 : 0. I. 86.5
November	1, 1906,	10 : 58 : 31 : 1. I. 84 5
December	21, 1906,	14 : 62 : 22 : 2. I. 87
February	3, 1907,	8 : 61 : 29 : 2. I. 83.5
March	8, 1907,	8 : 61 : 30 : 1. I. 84.
November	3, 1907,	4 : 42 : 49 : 5. I. 70.5

Case VIII. A female patient, had remained at work as a nurse without being conscious that she was seriously ill until extensive pulmonary tuberculosis had developed. Rather dense tuberculous lesions, both upper lobes, scattered lesions of left lower lobe. Widespread catarrh but to the present time no evidences of extensive consolidation or breaking down of the lung. Temperature nearly always normal. The general appearance, with rest, became that of health. Sputum loaded with tubercle bacilli. Cultures of the sputum after washing, were sterile. Arneth count, November 18, 1907: 22:59:16:3:0. I. 89.

The two preceding cases, in which mixed infection is almost certainly absent, are believed to prove that the toxins of tubercle directly affect the neutrophiles.

Case IX. A patient who had had pulmonary tuberculosis in 1900, after a winter in California during which he had had a constant cough with expectoration, and had been overworked, fearing a recurrence, presented himself for examination in March, 1907. Physical examination of the lungs showed no signs of activity. After a rest of several weeks, the Arneth count was 1:32:46:21:0; I. 56. He was advised to resume work less strenuously and has since remained well.

Case X. A soldier on duty as a clerk, a tall, thin young Irishman, coming up for examination for promotion, was subjected to a physical examination in the course of which there were found some doubtful indications of pulmonary disease. His color and the configuration of his chest tended to corroborate the probable diagnosis of pulmonary tuberculosis. The blood count by the Arneth method on February 7, 1907, gave 2:19:57:20:2; I. 49.5. In view of this excellent count, it was decided to pass him physically. His health has since been very good.

Case XI. A soldier sent here with the diagnosis of tuberculosis had been found to present evidences of pulmonary involvement, and had a cough with purulent expectoration. Tubercle bacilli were, however, never discovered and his general condition appeared to be excellent. On examination, areas of moist râles were found in the right upper and left lower lobes.

Arneth counts:

October	19, 1906,	2 : 24 : 50 : 22 : 2. I. 51
January	3, 1907,	1 : 18 : 56 : 22 : 3. I. 47

He was returned to duty, gained distinction as a ballplayer, and has remained for a year an exceptionally fine specimen of healthy manhood.

Case XII. The patient was admitted on July 24, 1906, much reduced in health with the diagnosis of pulmonary tuberculosis. The lungs, however, did not give evidence of disease further than a bronchitis. The history appeared to point to a precedent attack of fibrinous bronchitis.

Arneth counts:

July	30, 1906,	7 : 42 : 33 : 15 : 3. I. 65.5
March	29, 1907,	4 : 25 : 55 : 15 : 1. I. 56.5
November	4, 1907,	5 : 31 : 53 : 11 : 0. I. 62.5

The patient went to duty in about six months and has since been most active, both bodily and mentally. Except for a slight recurrence of fibrinous bronchitis, he has remained perfectly well.

Case XIII. A patient who had been treated for several years in sanatoria in various parts of the United States, after a residence of some months in the vicinity, was admitted to the hospital on December 15, 1906. At that time he complained of being too weak to walk. The pulse was accelerated and the digestion poor. Temperature usually normal. Nutrition very good. Physical examination showed an old lesion involving upper lobe and upper portion of lower lobe, left lung, with a small cavity in upper lobe, but no signs of activity. The question that presented itself was whether the weakness, digestive disturbances, and irritability of the heart might not be due to a masked recurrence of tuberculosis. Upon inquiry into the patient's habits it was learned that he had been advised to eat as much food as possible and that his wife had been systematically stuffing him. The unfavorable symptoms were ascribed to overfeeding, and the patient was treated accordingly. This view of the case was corroborated by the Arneth count:

December	21, 1906,	4 : 39 : 50 : 7 : 0. I. 68
March	29, 1907,	1 : 33 : 55 : 10 : 1. I. 61.8

The patient left the hospital on June 3, 1907, much improved, except for an attack of otitis media. His present condition is understood to be very good. Attention is invited to the improvement which took

place in the Arneth counts notwithstanding, or perhaps it would be more correct to say because of, a considerable reduction in the amount of food consumed.

THE DIAGNOSIS AND TREATMENT OF EARLY ECTOPIC GESTATION.*

By ABRAM BROTHERS, B.S., M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF GYNECOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING GYNECOLOGIST TO BETH ISRAEL HOSPITAL AND TO THE YORKVILLE HOSPITAL FOR WOMEN AND CHILDREN.

The subject of ectopic gestation has grown so threadbare, through constant repetition in recent years, that it has required an effort of presumption on my part to sit down and prepare the present paper. Nor would I have done so had I not felt that we have not yet reached the limitations of our knowledge concerning it, particularly in regard to its diagnosis and treatment. For my own selfish reasons, in great measure, did I therefore grasp at this opportunity to arrange the material which has come my way in the course of the last dozen or more years, and, without attempting to give a statistical review, or a thorough report of all my cases, I have tried to make a careful analysis and study of the subject in hand. The present paper, therefore, being a purely personal study, I have abstained from consulting the literature of the subject, and I have confined myself entirely to the results of my own experience.

Early ectopic gestation, confined to the first weeks or months, shows different varieties and conditions on the operating table. Concisely stated, the actual pathological picture ranges between nothing apparently wrong with a Fallopian tube up to a fetus and placenta in the abdominal cavity. Some of the lesions are so minute that even the pathologist with the slides under the microscope can hardly make the diagnosis. Ordinarily a swollen or ruptured tube with more or less free blood in the peritoneal cavity represents the conditions present. An ectopic gestation may present simply an unruptured Fallopian tube containing an ovum or blood clot, and discovered accidentally on opening the abdomen. In the vast majority of cases, however, something has actually happened to disturb the ovum in its tubal bed—usually either a tubal abortion or a tubal rupture. In these cases, when the tubal contents have not been discharged into the peritoneal cavity, a hemorrhagic condition of the tubal interior will be seen, or a clot may be discovered adherent to the fimbriated end of the Fallopian tube, which may apparently otherwise show no gross lesions; or the embryo or fetus may be discovered among the clots and free blood of the peritoneal cavity. In these latter cases the fetus may continue to live and the case may go on to one of abdominal pregnancy. The same result may ensue after rupture between the folds of the broad ligament. A true example of ovarian pregnancy I have never as yet met. Pelvic hematocele is present in most cases of ectopic gestation.

For clinical purposes our knowledge of the microscopic and macroscopic appearances helps us little in making a diagnosis between tubal abortion and tubal rupture, although a probable diagnosis can at times be ventured. The signs of a large intraperitoneal hemorrhage are not sufficient, according to my experience, to determine the differentiation. Nor is it possible by any means at present at our disposal to tell positively before operation or autopsy whether the pregnancy is of the tubouterine, tuboovarian, isthmic or abdominal varieties. Nor do I know of any method by which we can safely say that a blood collection in the pelvis is either a pelvic hematocele or a pelvic hematoma, excepting that my operative experience teaches me that we seldom meet a pelvic hematoma—at least rarely—without the presence of blood in Douglas' cul-de-sac or in the peritoneal cavity at the same time. At some future day we may know these things, but for the present we are ignorant of these finer details in diagnosis.

In the attempt to make a diagnosis of ectopic gestation a careful previous history is desirable. The age of the patient, period of married life, nature of menses previous to and since marriage, the number of children or abortions, including their nature and postpartum ailments—all should be inquired into. The possibility of gonorrheal or puerperal infections, of endometric or adnexal disease should be sought for in such previous history. Previous operations—especially curettages—should be noted. In taking note of the present illness, the mode of onset—particularly if an attack of syncope is referred to—should be analyzed. Symptoms pointing to the possibility of an early pregnancy and an impending or an incomplete abortion are of peculiar value in the history of the case.

My own observations regarding these various data are as follows: While the average age at which ectopic gestation was noted was 30 years, it has been my experience to operate the youngest case at the age of 18 years and the oldest at 44. The period of married life extended over as short a period as three months, as a minimum, and twenty years, as a maximum. One out of every four women had never been pregnant, and one-third of the remainder had given birth to one child only. So that the element of sterility on which so much stress was laid by the earlier writers is not of absolute importance as a predisposing factor. Still it is of interest to note that in one-half of my cases the time elapsed since the last confinement, in those women who had borne children, was estimated at an average of four years. The range of this period of relative sterility extended between six months and twelve years. In the primary sterility cases I have operated women as recently as three and four months after marriage. While not able to give exact figures, an unusually large number of my cases gave evidence of previous uterine disease, and, in many of them, a distinct gonorrheal infection could be established. Ectopic gestation is frequently overlooked because a woman is nursing her last child. This was the case in five of my recent operations. While a history of skipped menses is to be sought for, it should be borne in mind that in 25 per

*Read at a meeting of the Harlem Medical Association, held on February 5, 1908.

cent. of the cases no such statement can be secured.

The most important subjective symptom seems to be the irregular uterine bleeding of which the patient complains. This symptom will be found predominating in nine out of every ten cases. I have never been able to convince myself that the chocolate-colored blood so frequently described is really pathognomonic. At times it was absent, or the blood was bright red, and, on the other hand, I have often seen such bleeding in cases of other pelvic disorders—particularly in cases of uterine mole. The bleeding may be slight or so profuse as to require vaginal packing. At times it is not even irregular.

Some histories indicate merely a condition of menorrhagia or prolongation of the last normal menstruation, to seven or eight or ten days. The usual condition, however, is one of spotting during a period of days, weeks, or even months.

With nearly equal frequency do the patients complain of pain in the abdomen. This will naturally vary in character and severity, according as it is due to the distention of a tube, its rupture, or the invasion and irritation of the peritoneum by escaping blood. The claim that this pain is characterized by shooting down a limb holds true in only a limited number of cases. Anyone who has had frequent opportunity to inspect the interior of the abdomen in ectopic gestation and note the kaleidoscopic variety of pictures present in the different cases will understand readily why the pain must be different in individual sets of cases. As a matter of fact, it may consist of a little backache, an epigastric heaviness, a sense of fullness on one side or the other of the abdomen; it may consist of vague, crampy, intermittent pains; or it may give rise to the most terribly sharp and cutting cramps, resulting in some of the most agonizing pictures of suffering which the physician is ever called on to witness. One woman told me to cut her open as quickly as possible, as one more attack of the pain she had gone through would certainly have killed her. When present on one or other side of the abdomen, pain gives us an important, but not infallible, clue as to the site of the ectopic gestation. In a number of my cases the ectopic pregnancy was on the side opposite to the side over which the pain was complained of. It is best to inquire as to the situation of pain as it occurred at the onset or very beginning of the ailment. The pouring out of blood with consequent irritation of the peritoneum may in the latter stages cause pain anywhere or everywhere within the abdomen.

The third important symptom, and one which occurred in three out of every four of my cases, was syncope. Some women never seem to acquire the habit of fainting, and such women either give no history of syncopal attacks or only refer to having suffered a faint sensation. In the majority of cases, however, the women do actually faint, and the symptom which may often direct your attention to the possibility of an ectopic gestation will at times be brought out by the circumstances that some neighbor or relative resuscitated the patient with alcohol or vinegar during a fainting attack.

The three cardinal symptoms—irregular uterine bleeding, cramps, or pelvic pains, and fainting spells—should direct the attention of the physician to the possibility of ectopic gestation, the diagnosis of which can then be substantiated or negatived by the physical examination. Uterine fibroids and incomplete abortion may also present these symptoms, but can usually be excluded because of the absence or insignificance of pain in the former and the profuseness of uterine hemorrhage in the latter. Other conditions which come up for exclusion will be considered later when referring to differential diagnosis.

Among the less frequent symptoms complained of are rectal and bladder symptoms. Thus one of my patients who called on me in my office hours, complained of difficulty in defecation, associated with girdling abdominal pains. A free evacuation of the bowels gave her entire relief of symptoms which had persisted during several weeks. The local examination, followed quickly by operation, revealed a moderately large collection of free blood in the peritoneal cavity, the result of a number of hemorrhages dependent on early ectopic gestation. Patients with pelvic hematocele often complain of pressure or pain in the rectum. Others refer to pain and difficulty in micturition.

One of my patients had to be catheterized a number of times by the family doctor. Vomiting may be due to the pregnant condition or may be a reflex from peritoneal iritation and due to free blood in the peritoneal cavity. Most patients complain of weakness, varying between a mild grade of debility and the most intense degree of physical prostration. After a spell of symptoms these patients at times feel so good that they refuse to submit to operation, and several women in my experience have insisted on returning to their homes, only to come down shortly afterwards in another attack. Thus, two of my patients, who left my service at Beth Israel and St. Mark's Hospitals, were, to my knowledge, subsequently operated upon at Mount Sinai Hospital, where my diagnosis was confirmed by the findings on the operating table.

The discharge of a decidual sac, as a diagnostic sign, is of great importance, especially if the microscopic examination has excluded the presence of chorionic villi. Unfortunately, in the majority of cases, it is either not expelled or it has been thrown away before being submitted to careful examination. In a recent experience with a physician's wife, who seemed to be unduly prostrated and who ran an afebrile course with a pulse varying between 100 and 120 per minute, the discharge of such a three-cornered sac from the uterus caused me considerable uneasiness until Dr. B. Sheitlis, after a hasty examination, assured me that he found chorionic villi.

The subjective symptoms and history of the case having suggested the possibility of an ectopic pregnancy, we proceed to note the objective findings before we make the diagnosis.

In the absence of associated septic peritonitis or of suppurating hematoceles, these patients seldom present a rise of temperature. While in conditions of shock after a large escape of blood into the peritoneal cavity I have occasionally observed a rectal temperature of 96° F. it is usual to find the temperature normal or perhaps elevated by one or two degrees—100.5° F. or 101.5° F. The pulse is very variable. It may be slow or rapid; it may be regular, irregular, or intermittent: it may be strong and full or it may be weak, thready, and compressible. Even in the presence of intense anemia from internal hemorrhage I have occasionally found the pulse slow—in one case the beat counted 60 per minute. Such a pulse I have frequently observed to become suddenly acceler-

ated up to 130, 140, or even 160 beats per minute. It is remarkable, however, how the most rapid and feeble pulse will improve as soon as the peritoneal cavity is opened and the intraabdominal pressure from a large blood accumulation is relieved. Hence, since many years, the condition of the pulse has been no contraindication to me to proceed forthwith to operate even in the most hopeless and desperate cases.

Having noted pulse and temperature, we next resort to inspection, palpation, percussion, and vaginoabdominal or rectovaginoabdominal exploration.

A glance at the face alone sometimes gives us a clue as to the condition present. On June 5, 1901, I was invited by an able colleague to see a woman who was thought to be dying from cardiac failure due to an old valvular lesion. The intense facial pallor led me to make a careful inquiry into a recent "miscarriage," and as a result of my vaginal exploration I operated that woman in the little dirty kitchen of a tenement house. That woman I saw five years later in perfect health, and I have reason to know that she is still alive and well. My friend, Dr. M. M. Berger, invited me to a case recently. On entering the sick-room, without having begun to inquire into the history of the case, I was struck with the intense anemia of the invalid's face and playfully suggested a snap-diagnosis of ruptured ectopic gestation. One hour later the diagnosis was confirmed on the operating table. I have had a number of similar experiences.

I merely refer to the value of inspection of the face as a strong clue to a suggestive diagnosis of ectopic pregnancy, not as a conclusive sign. The anxious expression, the extreme pallor of the face, skin, lips, and nails, the rigid horizontal decubitus, the tendency to drop into a syncopal state, are all indicative of collapse due to intraabdominal bleeding. With a history of pregnancy the diagnosis is practically complete, provided there is no sign of large external hemorrhage. In walking cases or those of mild character, the anemia is insignificant. Only in the worst cases will dyspnea, or air-hunger, be present, and, with the cold, clammy skin and imperceptible pulse, will it be of the most ominous significance. Exceptionally the features may present a pleasant and smiling appearance, even with a ruptured tube, and I have in mind the case of a doctor's sister whose cheeks were actually of a rosy hue.

I have had a number of blood-examinations made in ectopic gestation cases, with results varying according to the amount of blood lost. In one case the leucocyte count was 16,600, and the polynuclears were rated at 85 per cent.; so that we can ordinarily look for an increase of both these blood elements. On the other hand, the red blood cells are usually diminished in number and the hemoglobin in amount. The greatest diminution in the number of red blood cells in any of my cases was recorded as 1,800,000 instead of the normal 5,000,000. The percentage of hemoglobin has varied in bad cases between 25 and 45 per cent.

In the average case inspection of the abdomen reveals nothing. Large intraperitoneal hemorrhages or the presence of peritoneal irritation or inflammation will result in an inflated abdomen. At times a distinct tumor will be seen situated in the median line or over Poupart's ligament. These are usually cases somewhat advanced in ectopic pregnancy.

In early cases or in nursing women or in multiparæ an inspection of the breasts gives us no valuable information. In primiparæ in whom the pregnancy has advanced beyond six or eight weeks, the alveolæ and nipples may present the usual appearances of pregnancy. Even colostrum may be obtainable on squeezing the nipples.

Palpation of the abdomen will in some cases discover a cystic or doughy, circumscribed tumor in the suprapubic or inguinal regions. Abdominal tenderness may be practically absent or present to an exaggerated degree. When present it may be localized over distinct areas or it may be generalized. With the associated rigidity one may correctly assume that a peritoneal irritation or inflammation is the underlying condition. In most cases gentle pressure elicits little pain which differentiates ectopic pregnancy from peritonitis due to other conditions. A frequent feature of this tenderness and rigidity when present is a tendency toward spontaneous abatement or disappearance within a short space of time or after a free evacuation of the bowels.

Percussion may yield only negative results or an exaggerated tympanitic note over the convexity of a distended abdomen. With blood accumulations in the lateral abdominal regions, a dull note may be elicited up to a certain point and an irregular contour may be mapped out by the percussing finger. Localized masses in the suprapubic or lumbar regions give a flat percussion note.

The vaginal examination usually gives us the greatest amount of information. Besides the bluish discoloration of the vulva and softness of the cervix—which are, by the way, unreliable signs in the early weeks of ectopic pregnancy—the discovery of a cervix pushed up against the symphysis by a non-sensitive liquid tumor, filling the posterior vaginal fornix, is a significant index of this variety of abnormal pregnancy. Very seldom do I resort to the use of the aspirating needle to establish the diagnosis. In fact, I believe that aspirating or opening the vaginal cul-de-sac adds to the risks of infection in case a laparotomy is to be performed. In many cases, however, a pelvic hematocele is absent or only a vague sense of fullness is felt. The uterus, as felt by bimanual examination, may be only slightly enlarged, or, in more advanced cases, be markedly enlarged. It is never as large as it should be in uterine pregnancy of the same period of gestation. Hégar's sign of softening at the anterior cervico-uterine junction is regularly present in the more advanced cases, but leaves room for considerable doubt in the earliest periods of ectopic pregnancy. Occasionally a co-existing fibroid-tumor formation may result in a disproportionate increase in the size of the uterus, as happened in one of my cases within the past year. The interior of the uterus may contain decidua and clots or it may be empty. The decidua, examined under the microscope, will show an absence of chorionic villi, excepting in those rare cases in which a uterine pregnancy has simultaneously existed. The uterine sound will in different cases enter to a depth varying between 2½ and 4 inches.

Vaginoabdominal or vaginorectoabdominal exploration may reveal a uterus which is in normal position or displaced anteriorly or perhaps laterally. Cystic or doughy masses may be felt filling one lateral half or the whole of the vaginal fornix. Seldom, if ever, to my recollection, have I felt a pelvic hematocele in front of the cervix,

although I have occasionally met blood accumulations in front of the uterine fundus. This is easily explained by the nature of the liquid collection and the presence of the bladder. Sometimes the coagulated portions of the blood gives an irregularly hard or nodular sensation to the examining fingers.

To assist in reaching a correct diagnosis of ectopic gestation in the early stages, we must remember that the disease may follow one of two diametrically opposite courses. The one variety presents the mildest type of symptoms and is most often confounded with an ordinary abortion or even a simple endometritis. The other variety pictures the most terrible collapse, with impending death, which the physician is ever called on to see, and has been properly called the "tragic" type. The second is only too often an advanced stage of the first and, in a great majority of cases, avertible if the proper diagnosis is made at the outset. Although a tubal mole or tubal abortion usually assumes the character of the mild type and a tubal rupture presents usually the signs of the severe type, I know of no fixed rule by which we can in any individual case determine the question with precision. Thus I have seen the most desperate cases of internal hemorrhage after a tubal abortion and only moderate degrees of hemorrhage from tubal rupture.

The onset in both varieties may be vague or indefinite and simply consist of a little irregular uterine bleeding with cramps, or it may attract attention by the occurrence of a sudden attack of syncope. In one case it occurred during the night while the patient was asleep. The woman awoke with a shriek, complained of a sharp pain in the abdomen, and fell back in a faint. Another woman suddenly toppled over in a faint while she was polishing the stove, crawled over to the door, summoned assistance, and then fainted away. A third woman went to the sink to vomit and her husband found her in a heap on the floor in an attack of syncope. A fourth woman fainted away after a fright. A fifth woman came to my office from Brooklyn and was seized with cramps in the elevated train. She dragged herself to my house, where I placed her on a couch and administered morphine hypodermically, to relieve her terrible suffering, until she could be properly transferred for operation. And so I could enumerate many more interesting experiences.

In the first clinical type, then, of early ectopic gestation, the patient may be up and about. A little irregular bleeding from the uterus, ascribed usually to an endometritis or following perhaps a skipped menses, a little cramp-like abdominal pain of varying character, an occasional sensation of faintness—perhaps repeated several times—may represent all of the subjective symptoms. An examination of the pelvis may discover a liquid collection in the posterior vaginal fornix or perhaps an indefinite immobile tumor of doughy consistency to the back or to either side of the uterus.

In the second clinical type the intense anemia of the face, lips, conjunctiva, and integument over the entire body occurring in a short space of time in a woman presenting a rapid and feeble pulse, and who seems to be passing through a series of syncopal attacks, will at once suggest the possibility of an internal hemorrhage. Because of the tender, rigid, and inflated abdomen the bimanual examination is, in my experience, usually unsatisfactory.

In both types of cases the history usually points to a skipped period, although this is not essential. Usually the woman has regarded herself as pregnant—perhaps after years of sterility—and the irregular uterine bleeding has been ascribed to an interruption of pregnancy. In several of my cases an actual attempt at criminal abortion had been made. In quite a few a curettage had been done by the family doctor. In exceptional cases the clinical manifestations follow no fixed type and defy the most careful and astute diagnostician.

Differential diagnosis must take into consideration ordinary uterine pregnancy with the usual symptoms of impending or incomplete abortion. This I find to be the most frequent source of error. A careful examination for the usual signs of pregnancy—especially a sufficient enlargement of the uterus, with the presence of Hégar's soft spot at the level of the internal os, and an absence of tumors or hematocele in the pelvis—will ordinarily be sufficient to establish a correct diagnosis. Of course the recognition of an ovum, embryo, or placental tissue in the discharges will leave no room for doubt. In case a question arises regarding such tissues, the microscope will settle the diagnosis.

In several instances I have known a diagnosis to have been made of cholelithiasis or appendicitis. In fact these conditions may be actually present simultaneously with ectopic pregnancy. Some years ago I diagnosticated cholelithiasis complicating an incomplete abortion in a case out of town, and the late Dr. Geo. B. Fowler diagnosticated the same case as one of ectopic gestation. On operation it was proved that we were both right, as the woman was suffering simultaneously from both conditions. The localization of pain over the appendix or gall-bladder with the classic symptoms characteristic of each will usually suffice for a proper identification.

A fibroid uterus can usually be differentiated by the history, and the stone-like hardness of the one or more tumors present. A few months ago Dr. M. Goldberger turned over to me for operation a case of abdominal pregnancy in which the diagnosis was very much obscured by the coexistence of a fibroid uterus.

Cases of pyosalpinx and hydrosalpinx are usually characterized by a different clinical history, although they give rise to frequent difficulty in differentiation from ectopic gestation. In one case of hydrosalpinx associated with an incomplete abortion the subjective and objective findings were so parallel to those met with in ectopic gestation that the correct diagnosis was only established after opening the abdomen.

Cystic ovarian tumors and intraligamentary cysts sometimes lead to errors, particularly when they are complicated by uterine pregnancy, or are wedged in the pelvis, or are twisted on their pedicles. The cystic feel, the globular contour, the lateral situation, and the mobility of ovarian cysts suffice ordinarily to distinguish them.

Pelvic abscess may at times strongly simulate an ectopic pregnancy. In case the presence of a febrile movement, exquisite tenderness over the mass, a markedly increased leucocytosis and polynuclear count fail to clear up the diagnosis the introduction of an aspirating needle will definitely settle the matter.

Some of the rarer conditions—such as a pregnancy in a one-horned uterus, or in one chamber

of a double uterus—may give rise to greater difficulties. The careful attempt to locate the round ligaments may assist in the differentiation; but this is usually a very difficult and, at times, an impossible thing even for the expert in pelvic examinations. We are consoled by the fact, however, that the same indication for prompt operative intervention is called for in both condihours.

The diagnosis of ectopic gestation—precise or presumptive—having been made, the treatment of ectopic gestation is surgical. It is true, however, that certain cases do get well without operation. Unless a case can be kept under the most rigid supervision it is neither wise nor safe to follow an expectant plan. We may at some future day be in a position to select those cases which go on to a spontaneous recovery from those who do not. With our present safe methods of invading the peritoneal cavity there is less danger in operating than in waiting. While many patients go on to recovery, others relapse and convert a previously simple case into one of colossal danger.

In former years I advocated vaginal section and drainage for pelvic hematocele. I now regularly open the abdomen in nearly all of my cases; a suppurating blood collection in Douglas' cul-de-sac would still induce me to resort to a vaginal incision. As for vaginal celiotomy I perform it occasionally in cases of ectopic gestation—usually when the diagnosis has not been clearly established previous to operation. My preference is in the direction of abdominal section in extrauterine pregnancy.

What can the general practitioner do in a case of ectopic gestation? The first essential procedure is to put the patient to bed and under proper surveillance. In mild cases this may be all that is necessary. Where internal bleeding is suspected, even though of moderate degree, an ice-bag over the hypogastrium, or over the painful area in the inguinal region is indicated. Morphine, given hypodermically, tends also to arrest hemorrhage or at all events it keeps the patient from tossing about too much. I do not give ergot, as its influence over muscular fiber may result in fresh rupture or hemorrhage. I have more confidence in adrenalin chloride solution (1-1000), when given hypodermically in doses of 10 minims each and repeated every three hours.

For shock hypodermic injections of strychnine and cardiac stimulants, rectal saline injections, hypodermoclysis, and intravenous transfusions are to be recommended. The head should be kept low in bad cases, the extremities bandaged, and oxygen given. Crile recommends as the best means at our disposal direct blood transfusion; but I have no experience with the method. Veratrum viride also has recently been highly lauded in the treatment of shock. If intense bleeding is profuse a vaginal packing will be of great service. Under no circumstances should a curettage be done, as this regularly does mischief in that it tends to increase intraperitoneal bleeding. I have reason to believe that at least one death, occurring shortly after curettage, of which I am cognizant and which was attributed to a possible puncture of the uterus, was due to this cause.

Shall we operate on a patient when in a condition of shock, or not? Surgical opinion is divided on this question. One recent writer has even gone so far as to claim that no woman has ever died from shock due to intraperitoneal hemorrhage consequent to the rupture of an ectopic pregnancy. Although most cases tend to rally there is sufficient evidence to prove that some of these patients do actually die from internal hemorrhage. As I know of no way to absolutely guarantee a cessation of bleeding I regularly advise operation if there is the slightest trace of a pulse. It is remarkable to observe how promptly a flickering pulse will gain in strength as soon as the intraabdominal tension is relieved after the peritoneal cavity has been opened. It is my usual custom in these very desperate cases to have one of my assistants start with an intravenous infusion just at the time when I am about to begin the operation.

Dr. Robert T. Morris, in recently describing the new principle in surgery, pithily remarked: "Get quickly into the abdomen and get out quickly." This corresponds with my practice for a great many years. In expert hands an operation for ectopic pregnancy on a patient in collapse should not consume more than fifteen minutes. Of course in the absence of shock or great debility one can work somewhat more leisurely. After removing the offending tube (perhaps, in addition, a fetus and placenta or even the uterus) as much as possible of the free blood and clots are rapidly mopped up and the abdomen closed without drainage. Leaving some blood in the peritoneal cavity, if the operation has been thoroughly aseptic, seldom results in harm. Our present knowledge of opsonins and phagocytosis teaches us to conserve the patient's vital forces by every means in our power, and this includes rapid work as a *conditio sine qua non*. I am not in favor of the practice of flushing the abdomen with hot saline solution or of leaving a quantity of such saline solution in the peritoneal cavity after the operation is completed.

In cases which do not call for an extreme degree of haste the abdominal wound may be closed in three layers. In desperate cases four or six worm-gut sutures passed through the entire thickness of the abdominal wound suffice. The patient is returned to a warm bed and the head kept low. If the patient is now carefully watched by a good nurse and a competent house officer, who will not kill the patient by the over-assiduous employment of hypodermatic injections of cardiac stimulants, it is surprising how many of the most desperate cases ultimately get well.

Of course the after-treatment will include bandaging of the extremities, hot-water bags to the limbs, perhaps another hypodermoclysis under the mammary glands or even a saline intravenous infusion, and rectal injections of hot saline solution repeated every three hours. I am fond of giving eserine salicylate gr. 1-60 hypodermically every three hours in alternation with the intelligent use of strychnine. After the patient has passed safely over the first twenty-four or forty-eight hours the bowels should be acted on in the usual manner. As soon as possible after the operation I reverse the patient's position, and have one end of the bed raised so that the patient rests upon an inclined plane. This gives a chance for retained blood to gravitate toward the pelvis where, if it is not absorbed, it may form a blood or pus collection, which can readily be reached later and be removed through a vaginal incision.

TREATMENT OF HYPERPHONIA (STUTTERING AND STAMMERING) BY THE GENERAL PRACTITIONER.*

By E. W. SCRIPTURE, PH.D., M.D.,

NEW YORK.

STUTTERING and stammering are terms loosely applied to one disease, which may be defined by its fundamental symptom, namely, excessive innervation of the vocal muscles. The disease might, in fact, be properly termed "superenergetic phonation," or "hyperphonia."† This disease has no connection with another disease of speech (called "Stammeln" in German) which arises from insufficient and mistaken co-ordination of the speech muscles due to defects in the vocal organs, in the nervous control, and in the ear. This form of speech defect may properly be termed "subenergetic phonation" or "hypophonia." Of this latter disease I shall say nothing further on this occasion.

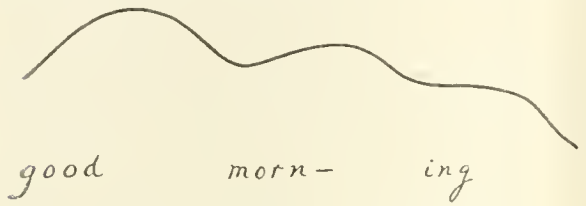

FIG. 1.—Fluctuating Melody in the Normal Voice

Symptoms.—The symptoms of superenergetic phonation may be classed as follows:

1. Cramps and hypertonicity of the breathing muscles. These may produce entire stoppage of the breath for a long time; the patient (and the hearer) must simply wait till the cramp passes off. I have had several cases in which the cramp has lasted 20 to 30 seconds.

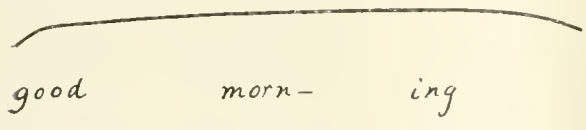

FIG. 2.—Monotony in the Stutterer's or Stammerer's (Hyperphonic) Voice.

These cramps may also produce short stoppages lasting a second or two and thus breaking up the speech. They may also produce irregular and improper breathing. The patient may take in a breath and be then seized with a cramp that expels it before he begins to speak. Such cramps also upset the person's habits of breathing, so that he finally ceases to breathe in a way proper for speaking. Along with the cramps and also without them there often arises a continuous superenergetic innervation of the breathing muscles. The patient breathes as a child learns to write; he tenses his muscles far too much and produces awkward and fatiguing movements.

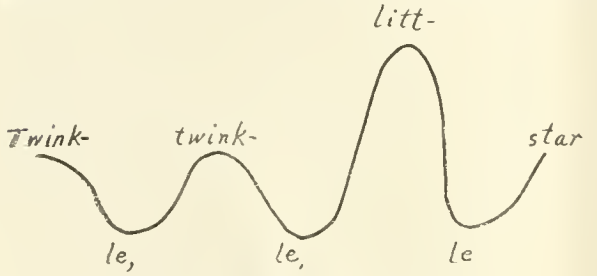

FIG. 3.—Excessive Melody Used in Teaching.

*Address before the New York County Medical Society, December 23, 1907.

†Scripture: "The Treatment of Stuttering." MEDICAL RECORD, May 11, 1907.

2. Cramps and hypertonicity of the laryngeal muscles. These sometimes go along with the breath-cramps and shut the larynx up tight so that no tone can be produced. More frequently we find hypertonicity of the laryngeal muscles, so that the flexibility of laryngeal action is lost. The vibrations of the vocal cords produce the tone of the voice, or the melody on which we sing or speak. In normal speech the melody is never constant; the voice is rising and falling at every instant (Fig. 1). About nine-tenths of the stutterers, however, speak in a monotone (Fig. 2); this is presumably due to the fact that it is easier to fix a group of tight muscles for one position than to keep them in easy action.

3. Cramps and hypertonicity of the muscles of pronunciation. The patients who forcibly contract these muscles for a moment or more are often called "convulsive stammerers." Those who have a series of cramps whereby they repeat a sound are usually termed "stutterers" or "re-duplicative stutterers." There is no essential difference and no sharp dividing line between the two classes.

4. Accessory cramps, contortions, and tics. These may arise from the spreading of the cramp over the side of the face, over the entire face, or over the entire body so that the patient jumps up and down.

Clinical Terminology.—The specific term for the disease would thus be "hyperphonia," and the three groups of symptoms would be called "respiratory, laryngeal, and articulatory cramps." The facial and bodily contortions might be termed "accessory spasms and tics."

Nature.—My experience has convinced me that the disease is a pure psychomotor neurosis; it is a habit over which the patient has no control. It might properly be called a "mental tic," or the result of a compulsive idea connected with speaking.

Causes.—Among the exciting causes we find irritations in the breathing organs (*e.g.* adenoids), imitation of other stutterers, injuries to the breathing organs, fright, etc. I have known a marked case to arise spontaneously in a neurotic child two and a half years old.

General Therapy.—The general therapeutic indications naturally include treatment of any nose or throat trouble that may be present, building up the general health, etc. Of these procedures I need say nothing further except to point out that they do not directly cure the stuttering (hyperphonia). It sometimes does occur that an operation for adenoids, for phimosis, or for anything else is followed by complete cure of the stuttering, but this, I believe, is purely a result of the patient's belief that the operation was intended for his disease.

Special Therapy.—Every case of hyperphonia requires special therapeutic procedures. My own experience has shown the following ones to be most effective:

1. Introducing melody into the voice. If the child is not very intelligent I first have him sing sentences on some familiar melody. He thus gets the idea that his voice must go up and down. Then he learns to speak sentences, sliding his voice likewise. But in most cases I begin at once to teach the person to speak melodiously, using little verses and sliding the voice somewhat excessively, for example, as roughly indicated in Fig. 3. Then the patient is taught to say, "Good morning," "How do you do?" "Please give me a glass of water," etc., all with excessive melody. Finally he is taught to speak and converse with melody.

This "melody cure" I have never read or heard of before; I stumbled on it quite by chance while try-

ing the various other cures. It is as effective as it is simple.

Fully half your patients will absolutely cease to stutter as soon as they learn to speak melodiously. You will be likely to have a repetition of one of my experiences. I demonstrated the cure to a man of fifty who had stuttered frightfully since boyhood and had tried all cures in vain; I intended merely to show him that it was possible to help him. To my surprise, in five minutes he ceased to stutter and went out of the office talking at ease. I tried to get him to come back afterwards, but he writes that he doesn't stutter any more and doesn't need any treatment.

Most people, however, require considerable practice before they can remember to speak melodiously, and the cure usually extends over periods ranging from four or five treatments to fifty.

The reason why this cure is so effective is that the stuttering habit is associated with one definite manner of speaking. It is not carried over to a manner of expression that the person *feels* to be utterly different. A stutterer never stutters when he sings, because singing is to him something quite different. A patient of mine never stuttered when he imitated an Irishman. The melody cure gives the stutterer a new manner of speech unconnected with his compulsive idea. It is like a surgical operation that removes an old voice and gives him a new one.

2. Developing expressiveness. Most hyperphonics are stiff and awkward in their manner of expressing themselves, in their postures, in their gestures, their thoughts, etc. For these defects it is well to exercise them in talking with gestures, in declaiming emotional pieces, in giving off-hand speeches on familiar topics, etc.

3. Distraction from the compulsive idea. Since hyperphonia is the result of a compulsive idea, it is necessary to get the mind off the idea during speech. The melody cure does this completely in many cases, but quite a number have difficulty in starting. To distract the mind at the moment of starting there are various effective procedures. I will only mention some that I have found specially effective. The patient is taught to beat time in a vigorous, snappy way; when he wants to speak, he brings the first syllable out with a snap on the first beat. In a more difficult case he learns to say "One—two" beforehand and bring the word out on the third beat.

Such a cure is often sufficient of itself. One little girl of twelve who came to me always repeated the initial sound of a sentence six times; she had no other difficulty. In two lessons she learned to beat time as she started to speak and had no more trouble.

Conclusion.—These procedures will permanently cure three-quarters of the stutterers and stammerers, if practice is given at first as often as possible and then at steadily increasing intervals. The treatment should last for fifteen minutes to half an hour. At first it should be given at least three times a week, then twice a week, then once a week, then once in two weeks, and so on. The patient should be warned that if he stops suddenly his trouble will probably return.

The care of the general health and the examination of the mind, nerves, and breathing organs are so important that only a physician can be considered competent to advise. For a case of stuttering the parent should send the child directly to the doctor. Unfortunately the doctor is very likely to prescribe a tonic and to say that the trouble will pass away in the course of time. Sometimes it does; generally, however, it steadily becomes worse, and the child's companions and parents by their taunts or nagging or scolding make his life a condition of torture to which Hades would be a relief.

It is quite true that many cases of stuttering are cured by teachers of singing and other persons; it is also quite true that sick people often fail to die when no doctor is around or when an osteopath or a "Christian Scientist" is called in. But "hyperphonia" is a disease. It is, we may even say, a serious disease. The patients do not die of it directly, but their lives are so filled with suffering that most of them wish they could. That some of them are cured by outsiders does not alter the fact that most of them are not. Under any circumstances a disease can be properly handled only under the direction of a physician.

Even this brief outline of the melody cure and the means of distracting attention will, I believe, enable many of you to treat cases without further practice. To those of you who wish further demonstrations I will say that a special clinic for speech defects is held as part of the neurological clinic at the Vanderbilt Clinic, and that nothing could give me greater pleasure than to show the methods to any who will honor us by attending.

FREUD'S METHOD OF PSYCHOTHERAPY.*

By L. PIERCE CLARK, M.D.,

NEW YORK,

SENIOR ATTENDING PHYSICIAN, HOSPITAL FOR NERVOUS DISEASES OF NEW YORK CITY; VISITING NEUROLOGIST TO THE RANDALL'S ISLAND HOSPITALS AND SCHOOLS, CONSULTING NEUROLOGIST AT THE MANHATTAN STATE HOSPITAL, N. Y.; CONSULTING NEUROLOGIST AT THE CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y., ASSISTANT NEUROLOGIST AT THE VANDERBILT CLINIC (COLUMBIA UNIVERSITY).

More than a key to the psychotherapeutic method of Freud is embraced in his trite truism in commenting on the different forms of psychotherapy. He says that "all are good that do good." At the present time Freud limits himself to the so-called analytic method for subjective reasons. He believes it is the only method capable of going beyond itself and leading to other fields of therapy. Freud's analytic method is often confounded with hypnotic suggestion. In reality analysis is directly opposed to suggestion. Suggestion technique takes no account of the origin and significance of symptoms, but only of the strength of the suggestion in its bearing on the pathogenic idea in the hope of arresting the latter. The technique of analysis on the other hand does not seek to introduce a new element, but to take away something, and to this end seeks to determine the genesis of the symptoms and the association of the pathogenic idea. Freud gave up suggestion as it gave little of permanent or lasting value. The cause remained and the whole disorder was but masked for a time.

Many regard Freud's analytic method as easy and self-evident, but no one who has carefully tested the latter has remained curious as to its intricate and difficult nature. One does not simply attempt to secure a confession. Such methods do harm rather than good. The individual soul is an instrument not so readily played upon. Freud cites the case of Hamlet and the courtiers as an evil example. One must agree with Freud that his method is inconveni-

*Read before the New York Neurological Society, January 7, 1908, as part of a symposium on "Modern Methods in Psychotherapy."

ent for the average physician. It should be employed only by the expert and then only on the most desperate and rebellious cases, refractory to other plans of treatment. A severe neurosis is held to be somewhat similar to a severe cachexia in this respect.

There are no hard and fast lines which we may lay down for the use of Freud's method. It is held that no one should be treated who has not a certain degree of education and character. No time should be spent on those applicants whose general worthlessness is blamed upon a disease state—"people who are not sick but foolish" in the language of Dana. The neurotic is not a degenerate, although the two may coexist. Freud's results show poorly in the neurotic degenerates. The method is of limited use here. Patients themselves must seek this treatment in good faith and not be urged thereto by relatives. It is not applicable to patients without keen insight into their disorders and therefore has limited use in the pure psychoses. While age is a factor, yet this can only be determined for the individual case. In a general way it is not applicable to those above fifty years of age. The patient then is no longer educible and the emotions are not plastic. Freud reports excellent results on many cases before puberty.

In those mental states in which, as for instance in hysteria, there is anorexia or some other of the gross and severe stigmata, the treatment must be withheld until the quiescent phase of the disorder is resumed. The field of usefulness of the method is not so limited as one is apt to think when bearing in mind that all chronic hysteria, impulsive states, aboulias, etc., are amenable to this special treatment.

While Freud assures us that there is no possibility of injury to the patient from his plan of psychotherapy, we can not agree with him. Even the best laid plan of excavating into the patient's subconscious being is sure in many instances to unearth revolting and perhaps many irrelevant memories that may take root in the conscious mind and require a special cure by Freud's specific treatment. Analytical psychotherapy of Freud is grounded on the unconscious psychical processes of the patient. With Janet the author refers hysteria back to unconscious fixed ideas. Unconscious is not used in the metaphysical sense. The treatment consists in translating the unconscious to the conscious and thereby in correcting deviations from normal psychical processes, and in removing from the patient the impulsions under which he labors. Conscious will presides over conscious cerebration, while on the other hand abnormal impulsion is founded on the unconscious.

The exposure and translation of the unconscious takes place amid a certain resistance on the patient's part; he has no desire for this innovation. The physician takes a hand in the resulting antagonism. If the automatic resistance of the patient can be overcome the patient has undergone a certain degree of education. It is at this point that Freud introduces his peculiar sex genesis of the minor neuroses. He believes that both education and culture have done much harm in this sphere to the neurotic. Sex is in the main the controllable etiological factor; the other factor, which is the constitutional make-up, is unalterable. The physician should be a man of morality, yet a "man of the world."

This sex idea of Freud's analytic method is grounded in his firm conviction that the sexual element is in the last analysis supreme as a factor in causing hysteria. Such questions as those of sexual desire and continence represent but one side of the matter. If this were all it would not be a question of disease, but of sexual excesses. The other side is represented by the sexual disinclination of neurotics, and the inability to love. Freud in tireless reiteration emphasizes the necessity of considering both the sexual alteration and sexual repulsion together.

One may illustrate the kind of cases treated by Freud's method as follows: A person has a painful experience or a series of experiences (as in Freud's notorious Dora case), usually sexual in character. The emotion thus aroused is accompanied by some bodily or verbal expression. The original emotion may then fade from view, but the expression of the emotion lives and recurs in consciousness. Recurrence of the expression may call up the emotion for a time, but eventually the expression may persist alone until the repressed emotion comes in evidence through some adequate natural cause. The expression-cause then ceases to recur.

The mischief caused by the repressed emotion is annulled if they are allowed to work themselves off in the conscious sphere by the exposure cure. One "lays ghosts by the same modern method."

A more definite analysis of the technique is as follows: Freud usually has the patient fully relax in a favorable environment, cuts off all sense stimuli. Then with hand on patient's brow he urges the patient to search the memory for any forgotten painful experience, usually involving sex. Under favorable circumstances such experiences are mentioned early in the examination, or if at first the patient resists, the "confession" when it does come, comes all the more sharply and clearly.

There can be no doubt that Freud's method is of great benefit in many cases, particularly in hysterias, but it is not widely applicable in general disorders of the minor neuroses until the sexual idea is eliminated, as Putnam's study proves. The method is very cumbersome, if ingenious, and ought to be modified in many cases to include the substitution or suggestion method of side tracking the morbid trend of thought. Subconscious memories are not handed down intact, as Putnam observes, but rather from a chain of association so that all present concepts are really new, however remote their origin. The past never really lives in the present.

Just as Freud's method is more susceptible of explanation on the theory of side-tracking a morbid trend of thought, so is it more readily applicable than hypnotism and an improvement in many respects over older methods.

The advantage of Freud's method over hypnotism, in eliminating the curiosity of the physician to the patient's disadvantage, is quite obvious. The linking together what the patient said and did in the past with the morbid state of the present is likewise advantageous.

Finally we may say that Freud has accomplished his results, but by cumbersome methods. It may also be noted that hardly any one, according to Freud's sexual theory, can escape the charge of being neurotic—either having too much or not enough sexuality.

I am sure you will pardon me for not citing the details of the cure Freud has rendered in any one of his cases, when I tell you that the hysterical Dora case occupies over 80 journal pages, and aside from its tedious length, is poorly suited for condensation.

REGENERATION OF BONE.

DESPITE the practical importance of the subject, considerable diversity of opinion exists as to the factors concerned and the processes operative in the regeneration of bone, particularly in connection with the repair of fractures. For the purpose of clearing up some of the existing obscurity and of reaching an independent opinion, Dr. Henry S. Wieder (University of Pennsylvania Medical Bulletin, September, October, and November, 1907) undertook an extensive series of experimental observations on dogs and rabbits. As a result of this study it was found that in the regeneration of bone all the various elements, namely, periosteum, cortex, endosteum, and marrow, assist in the process. These in their activities appear to bear a more or less reciprocal relation to one another, so that the absence of any one may be compensated for by the presence of the others.

The activities of the endosteum and the medulla, it was shown, can be brought into play by slight stimuli. The periosteum, even when proliferated, is incapable of forming osteoid trabeculæ unless in close contact and union with previous bone-formation or calcareous salts. Periosteal bone-formation is usually preceded by superficial absorption of the cortex through the action of osteoclasts. These possibly liberate lime-salts in the tissues for the osteoblasts again to precipitate in the surrounding hyaline matrix. Cortical bone-forming activity does not manifest itself until after considerable absorption of the cortex has occurred, so that it may be due either to the liberation of bone-cells that take on new activity and again precipitate the liberated calcium salts in new situations, or to the opportunity for the ingrowth of endosteum into the widened spaces.

In case of unimpaired regeneration bone defects are filled with trabeculæ and spaces that originally run at right angles to the line of the bone, but rearrangement occurs in the later stages, with a change in the direction of the canals in the new bone. This is the normal outcome of cortical activity. The medulla assists in forming osteoid trabeculæ by means of a skeleton framework along which the trabeculæ form, and also, possibly, by the activities of some of the marrow-cells. The deposit of calcium-salts in certain lines to form trabeculæ is not due to blood-vessels, as the spaces between the trabeculæ until some time after they have formed do not contain blood-vessels.

Cartilage is a pathological but constant feature in the repair of complete fractures. It is not found in connection with normal regeneration free from extrinsic influences. The formation of cartilage may have some relation, direct or indirect, to the masses of fibrin found in the region of the line of fracture, or it may represent a retardation in the development of osteoid tissue as a result of poor nutrition. In case of complete fracture the amount of cartilage present depends mostly on the angularity of the fragments, and it is always found in the shape of a wedge on the internal aspect of the angle. Complete fractures are slow in reaching final union, so that in the event of vicious union they may be safely rebroken up to nine months, and even longer, without danger of fracturing the bone in another situation. They may even be made to yield to traction in the proper direction.

Usually sufficient callus is formed on the inner side of an angularly deformed fracture almost to reestablish the original line of the bone from one joint to the other, but with commensurate shortening. In case of subperiosteal fracture the repair probably is mostly effected from the endosteum and medulla because of the extravasation of blood into the medullary canal, resulting in greater injury to the medulla than to the periosteum. The endosteum and the medulla are probably the most important factors in the repair of greenstick fractures.

Bone-regeneration after subperiosteal resection is usually cartilaginous when sufficient time has not elapsed before the operation for the formation of periosteal osteoid trabeculæ. A strip of healthy bone left between the two fragments of resected bone hastens osteoid regeneration. Healthy medulla sutured between apposed surfaces of periosteum hastens considerably the regeneration of bone. The process of repair in complete fractures may be divided into five stages, namely, infiltration, temporary callus-formation, reorganization, permanent callus-formation, absorption. Similar changes are probably found in the human subject also, with slight differences owing to the size and nature of the species. The deeper layer of the periosteum, the endosteum, the tissues lining the Haversian canals, and the bone-cells are probably all related or identical tissues, exhibiting different activities because they exist under different physical conditions. Cartilage is converted into osteoid tissue in several different ways in accordance with the age of the cartilage and the stage of the fracture. Osteoid tissue, when viewed in ground section, is not as dense in structure as normal cortex, and it has a deeper yellow tinge, probably by reason of some difference in chemical composition. Specimens of bone with their soft parts attached can be ground to microscopic thinness, but they possess no advantage over decalcified specimens except for the demonstrating of canaliculi. Investigations into the regeneration of bone, when not accompanied by microscopical study, are untrustworthy and often deceptive.

MEDICAL VS. SURGICAL TREATMENT OF GASTRIC ULCER.

THE difficulties attendant upon a solution of the best methods for the treatment of gastric ulcer are great. The uncertainty of its clinical course and

the different opinions as to what constitutes a cure render statistics concerning therapy most confusing. In a general way the methods of treatment are either medical or surgical, both having their advantages and disadvantages. In a paper in the *American Journal of the Medical Sciences* for December, 1907, Dr. John Musser presents a study based on 1,871 cases of gastric ulcer and demonstrates the relative values of the surgical and medical treatment, showing that each has a field, and also in which field the respective methods apply. He differentiates between simple ulcer and ulcer with complications, they having an entirely different clinical expression, although both are liable to hemorrhage and perforation.

Taking up first the question of simple uncomplicated ulcer, he found that the statistics uphold his contention that the immediate and remote results are far better after medical than after surgical treatment. The latter usually consisted of a gastroenterostomy which at times relieved the symptoms temporarily, but did not remove the cause of the patient's suffering any more than medical treatment. He found that the mortality of simple ulcer varied with different observers irrespective of the method of treatment, ranging from three to twelve and a half per cent., after medical treatment and from eleven and a half to twenty per cent. after surgical treatment. As regards the complications of gastric ulcer (stenosis, adhesions, hourglass contraction, dilatation, pyloric spasm), he found them in forty per cent. of all cases, appearing always later in life and usually in persons giving a previous gastric history of from five to ten years. When these become intolerable or perilous he considers the case one for surgical treatment, as the statistics show that the latter gives far better and more permanent results than medical treatment. In speaking of hemorrhage he estimates its occurrence in the course of gastric ulcer at from fifty to eighty per cent., the majority of the patients requiring no special treatment. Seven hundred and sixty out of 1,871 patients, had sufficient hemorrhage to imperil life, either because of frequent small bleedings or because of one or more large hemorrhages. The statistics support Musser's observation that acute large hemorrhages treated medically are attended by less mortality than those treated by surgical means; medical 23.1 per cent., surgical treatment, 42.8 per cent. A chronically bleeding ulcer leading to grave anemia on the other hand, he claims is cured more frequently by surgical than by medical means; mortality after medical treatment, 28.5 per cent., after surgical 22.4 per cent. Age and sex did not predispose to success or failure in either line of treatment. With respect to perforation, improved abdominal technique has led to remarkable success. Out of 586 cases with perforation 481 were operated upon with a mortality of 34.3 per cent., while death occurred in 54.5 per cent. in the unoperated cases. In the extremes of life the mortality was higher; the shorter the interval between operation and perforation the greater was the percentage of cures.

Of the various operations, gastroenterostomy was performed more frequently than any other, and while some operators reported a mortality of less than three per cent., the average mortality of all operators was 23.8 per cent., which is lower than after excision. Musser states that those patients who survived the operation for perforation were permanently cured more frequently than patients without perforation treated by any of the other methods. As the closing of a perforation practically amounts to excision it would seem that this is the ideal form of treatment, but we must not lose sight of the fact that this is difficult when the ulcer is on the posterior wall of the stomach or when there are several ulcers present. We are, therefore, still safe in stating that simple ulcer is a medical affection, while a complicated ulcer is a disease which as a rule calls for surgical treatment.

THE SIGNIFICANCE OF THE PRESENCE OF TUBERCLE BACILLI IN FECES.

Experimental studies regarding the excretion of bacteria have shown that the subcutaneous or intravenous injection of various forms of bacteria may be followed by the appearance of the organism in the feces without any evident lesion being present in the mucosa of the intestine. Thus, too, typhoid bacilli are found in the urine without any lesion of the genitourinary tract, and the milk of a cow is found to be infectious without disease of the udder. That the tubercle bacillus may be present in the feces without any intestinal lesion, being purely in process of excretion, and that its presence there may be of value in diagnosing tuberculosis elsewhere in the body, has been shown by R. Rosenberger in the *American Journal of the Medical Sciences* for December, 1907. He inoculated rabbits and guinea pigs subcutaneously with attenuated human tubercle bacilli and found the bacillus in the feces four days later; an autopsy seven weeks later revealed no intestinal lesions. Control animals showed no acid-fast bacilli in the feces. He also examined the feces of sixty patients diagnosed as tuberculous and of 612 persons in whom there were no clinical evidences of tuberculosis, but who suffered from various other diseases. In all of the former and in sixty of the latter the bacillus was found. Two-thirds of the cases in which the bacillus was found in the feces and in which no tuberculous lesion was diagnosed during life came to autopsy; while these patients succumbed to some other disease, they also showed tuberculous lesions. Thus, too, all the patients in whom a clinical diagnosis of tuberculosis was made and whose feces showed the tubercle bacillus revealed tuberculous lesions at autopsy. While it is the rule to find the bacillus in the feces in well-defined cases of pulmonary and intestinal tuberculosis, they may be present there irrespective of a pulmonary or intestinal lesion, as is proved by the fact that Rosenberger found them in general glandular involvement, in meningitis, in coxitis, and in Pott's disease. In acute miliary tuberculosis, diagnosed or not clinically, the bacillus was found in the feces in every instance.

Rosenberger holds the finding of the tubercle bacillus in the feces will determine the diagnosis in doubtful cases. In certain cases an ascites, the nature of which could not be determined in any other

way, he was able to diagnose positively as tuberculous, the diagnosis being substantiated later at operation. As a result of his work he believes the contention of some investigators that acid-fast bacilli are found in feces of healthy individuals is erroneous. He lays great stress on excluding the smegma bacillus. Admitting that the tubercle bacillus cannot always be demonstrated in the stools, even when there is undoubted intestinal tuberculosis, he feels positive that when an acid-fast bacillus, which morphologically represents the tubercle bacillus, is found in the feces of any individual, tuberculosis exists in some part of that person's body.

Cancer Statistics.

One of the greatest obstacles encountered by the student of the literature on carcinoma consists in the difficulty of correlating the figures given by different authors owing to the varying methods of formulating statistics. The desirability of uniformity in this regard has often been pointed out, and among those who have endeavored to secure the adoption of a definite system the well-known gynecologist Professor Winter of Königsberg has been especially active. At several of the recent German gynecological congresses he has urged the formulation of a standard method of computation and now in the *Zentralblatt für Gynäkologie*, February 8, 1908, he outlines such a scheme and requests those interested to correspond with him concerning it. The following are the principles which he believes should underlie the estimation of results. The mortality figures should comprise all deaths after the operation which would not have occurred without this, that is including sepsis, heart failure, embolism, pneumonia, etc. A case is to be considered as "operable" when it has been possible to complete a radical operation. The calculation of the ultimate results is to be made on a basis of a five-year period without recurrence. In computing the results of operation the number of radical operations is used, and from this there are deducted the deaths due to the operation, the number of patients who have disappeared, and the number of those who have died of intercurrent affections before the five years have elapsed. In determining the percentage of cures there must be taken into consideration the number of inoperable cases, the number of those dying of the operation, and of those having recurrences, while there are to be excluded those refusing operation, those disappearing from observation, and those dying of intercurrent diseases. It would also be desirable to have writers in discussing their results indicate the number of their patients falling into each of the above classes as then the figures could always be utilized in any way desired and comparisons be made with the results of other operators. While Winter's appeal is directed especially to the gynecologists, what he says applies with equal force to all fields of operative work on tumors, and the adoption of some such uniform basis of calculation could only be of benefit.

A Simple Serum Test for Syphilis.

The belief is now becoming general that Wassermann's serum test for syphilis, when positive, points to active syphilis, though a negative reaction does not exclude the latter. His method, however, is too complicated for general practice, so that a simple method as suggested by E. Klausner in the *Wiener klinische Wochenschrift* of February 13, is deserving of our consideration. He obtains five c.c. of blood by scarifying the patient's back and using a small suction pump. The blood is then centrifuged and two-tenths of one c.c. of the serum, together with seven-tenths of one c.c. of distilled water, are placed in a glass tube one-half a centimeter in diameter and seven centimeters high. After thorough mixing, the solution is allowed to remain at room temperature. In all of thirty-one syphilitic patients examined a precipitate from two to four millimeters in depth was formed in from two to fifteen hours. Most of these patients were in the second stage, though five were in the first stage and two showed syphilitic gumma. Sera from twenty-three non-syphilitic patients suffering from other diseases showed no precipitate at the end of fifteen hours and only a very slight one at the end of twenty-four hours. Two patients with croupous pneumonia and one with typhoid fever gave a positive reaction, *i.e.* a heavy precipitate in fifteen hours or less when the serum and distilled water were used in the proportion mentioned (1:3.5). When, however, five or ten times as much water as serum was used these same patients showed a negative reaction, while the syphilitic patients still gave a positive one with these dilutions. The number of patients examined is still too small to serve as a basis for positive conclusions as to the value of Klausner's test, but the method is so simple that it is worthy of trial.

White and Red Meats.

It was largely as the result of the work of Offer and Rosenquist, published in 1899, that the current view regarding the difference between the red and the white meats as affecting metabolism was modified, and it came to be generally accepted that from the analytical standpoint at least there was but little distinction to be made between them. This belief, although apparently founded on reliable scientific observation, has not been entirely in accord with the more or less empirical experiences of those accustomed to treat large numbers of patients suffering from such diseases as gout and nephritis. It has been pointed out, notably by Senator, that while Offer and Rosenquist's observations showed that as far as raw meat was concerned, the difference between the amounts of nitrogenous extractives and bases in the red and white varieties were so slight as to be practically negligible, it remained to be demonstrated that the process of cooking and the manner in which this was done did not alter the conditions. This question has been taken up by Adler (*Berliner klinische Wochenschrift*, February 24, 1908), who presents the records of analyses of numerous meats both in the raw and cooked condition. While his results on raw meats correspond closely with those of the previous investigators, he found on comparing veal and beef that both frying and boiling caused the extractives of the former to be reduced to about one-fifth of their raw amounts, while with the beef the difference was unimportant. Analyses of other meats gave similar results, and he concludes that in the cooked condition there is a sufficient difference between extractive content of red and white meats, particularly beef and veal, to justify a distinction between the two. Cooking therefore seems to cause white meats to lose more of their extractives than is the case with red, and taking for granted a deleterious property on the part of the nitrogenous ex-

tractives, the clinical observation that in certain maladies red meats are injurious finds analytical confirmation.

Gastric Secretion in Nephritis.

The behavior of the gastric secretion in nephritis has been the subject of considerable dispute. On the one hand it has been claimed that the hydrochloric acid is always diminished in this disease, while other observers have maintained that the disturbance of gastric activity present in the cases on which this view was founded has been due to chronic gastric congestion or was merely the secondary functional change to be noted in many other chronic or wasting disorders. A suggestion in regard to the explanation of this difference of opinion is made by Axisa (*Zentrallblatt für innere Medizin*, February 29, 1908). Together with Stejskal he had previously found that the extirpation of a kidney in the dog was always followed by an immediate and pronounced drop in the HCl secretion, and he now reports a series of forty cases of nephritis of various types in which careful gastric analyses were made. In most of these hydrochloric acid secretion was diminished even though there was no evidence of chronic gastritis or of circulatory disorders of the stomach. In five cases, moreover, repeated analyses were made and the results show a considerable fluctuation in gastric secretion. Whenever there were symptoms of renal insufficiency or of uremic nature the HCl values fell, only to rise again as the renal picture improved, and it is in this variation that the author sees the explanation of the discrepancies between the views of different observers. He believes that there is a parallelism between the gastric and renal functions, so that in the presence of uremic manifestations the gastric secretion decreases and then returns to the normal when the kidney condition improves. While, as Senator has claimed, the subacidity may not be characteristic of nephritis, it appears to be closely associated with uremia.

News of the Week.

A New Red Cross Organization.—The American National Red Cross is organizing a trained volunteer army for first aid to the injured under the name of the Grand Legion of the Red Cross. The first "relief columns" of this Grand Legion were formally organized January 22 in Brooklyn under the direction of Dr. Glentworth R. Butler and with the assistance of Major Charles Lynch, Medical Department, U. S. A., who has been especially detailed by the Surgeon-General. The members of the legion will be taught to give first aid under all conditions, and will be prepared to serve as a body in time of local need or in war, in the latter case under the medical department of the army. Their function will also be educational and preventive, since their work will be both indirectly and directly a crusade against preventable accidents, which make up probably two-thirds of the 10,000,000 accidents a year in the United States, by which more than 60,000 lives are lost. Each relief column will eventually have attached to it a relief corps of women trained in first aid and home nursing. The men will be uniformed. Further information may be had at the New York State Branch, No. 500 Fifth avenue.

Chicago Pasteur Institute.—This institute recently issued a report covering the number of cases of hydrophobia treated from the time of its inception, July 2, 1890, up to December 1, 1907. The number of patients that received the anti-hydrophobic treatment was 3,130. Of these, 2,779 persons had been bitten by dogs, 102 by cats, 109 by horses, 28 by skunks, 6 by wolves, 36 by cows, 12 by calves, 2 by burros, 4 by coyotes, 1 by a rat, 4 by mules, 6 by pigs, 2 by sheep and 38 were infected by hydrophobic human beings. Of the individuals treated, 1,685 were persons bitten by animals found to be rabid by microscopic examination of the brain or inoculation test or by the death of persons or animals bitten by the same animal; 1,109 had been bitten by animals found to be rabid by symptoms shown in life, and 336 had been bitten by animals strongly suspected to be rabid. Seven deaths are reported, a mortality of 0.22 per cent. Of the seven individuals who gave up the treatment, two were subsequently taken with rabies and died.

The Rockefeller Institute for Medical Research.—Dr. L. Emmet Holt, Secretary of the Rockefeller Institute, announces that the Institute purposes to award for the year 1908-1909 a limited number of scholarships and fellowships for work to be carried on in the laboratories of the Institute in New York City, under the following conditions: The scholarships and fellowships will be granted to assist investigations in experimental pathology, bacteriology, medical zoology, physiology and pharmacology, physiological and pathological chemistry, and experimental surgery. They are open to men and women who are properly qualified to undertake research work in any of the above mentioned subjects and are granted for one year. The value of these scholarships and fellowships ranges from eight hundred to twelve hundred dollars each. It is expected that holders of the scholarships and fellowships will devote their entire time to research. Applications accompanied by proper credentials should be in the hands of the secretary of the Rockefeller Institute not later than April 1, 1908. The announcement of the appointments is made about May 15. The term of service begins preferably on October 1, but, by special arrangement, may be begun at another time.

To Safeguard the Hudson.—Assemblyman Robinson's bill, providing for a State Commission, to be known as the Hudson River Purification Commission, has passed the Assembly. The measure authorizes Governor Hughes to appoint two citizens, who with State Health Commissioner Eugene A. Porter, will constitute the Commission, which shall proceed at once to make investigations to determine the causes of the pollution of the Hudson River and its tributaries, and to determine what, if anything, can be done to prevent such pollution. Members of the Commission will receive actual expenses, but no salary, and the Commission is to report to the next Legislature. An appropriation of $6,000 is made for expenses.

Digital Insalivation.—Under this appellation the Medical Society of City Hospital Alumni of St. Louis condemns the practice of moistening the finger in the mouth before handling leaves of paper or other dry substances, and which is very common among salesmen, postoffice employees, cashiers, and others who come in contact with the public. Resolutions condemning the practice and urging the endeavor to restrict it were adopted at a recent meeting and sent to the Postmaster-General, the St. Louis postmaster, and the Health Department. Passengers on the trolley cars of this city no doubt have often felt a qualm before accepting a transfer plentifully smeared with the conductor's oral secretions, and not long ago a bacteriologist was

able to demonstrate the presence of tubercle bacilli on a transfer received from a tuberculous conductor.

Administration of Illinois Institutions.—At a joint meeting of the Chicago Medical Society and of the Physicians' Club of Chicago, held March 13, the administration of State institutions was freely and thoroughly discussed by Mr. William T. Graves, Secretary of the Board of State Charities, Dr. Frank P. Norbury, William B. Moulton, Dr. Richard Dewey and Emil G. Hirsch. The meeting ended with a resolution offered by Dr. John M. Dodson, commending and endorsing the work of the State Board of Charities.

Cartwright Lectures.—The Cartwright Lectures of the College of Physicians and Surgeons will be given by Professor James Ewing, of Cornell Medical College, on March 25, 27, and 30, at 5 o'clock in the afternoon, at the New York Academy of Medicine. The subject of the lectures is "Acidosis and Associated Conditions," divided as follows: First lecture, March 25, "Experimental Basis of the Doctrine of Acid Intoxication, Diabetic Acidosis. Second lecture, March 27, Physiological Chemistry of Acetone Compounds. Third lecture, March 30, Clinical Forms of Acidosis.

A Biography of Lafcadio Hearn.—Dr. George M. Gould in his book on Hearn, shortly to be published by George W. Jacobs & Co., presents a remarkable study of the man and his work, dealing with both the good and the bad in his character and the strong and the weak points in his writing. As this biographical and critical study of the gifted but unfortunate writer is from the pen of one who knew him intimately, it should prove of peculiar interest, not only to Hearn's special admirers, but to the general public as well.

Congestion of Population Exhibit.—An exhibit to illustrate the congestion of population in this city is being held in the American Museum of Natural History, and several conferences to discuss municipal problems have taken place, at which Governor Hughes and other prominent persons have delivered addresses. The exhibition closes on Sunday, March 22.

Proprietary Remedies in Philadelphia.—At a meeting of physicians and pharmacists held in Philadelphia on March 11, among those who said that there was danger in going too far in the crusade against proprietary remedies were Dr. S. Solis Cohen and Dr. Hobart A. Hare. One of the speakers, Dr. Christopher Koch, said that an examination of 27,000 prescriptions had shown that of late the percentage of prescriptions for proprietary articles had fallen from 20 per cent. to 13 per cent.

Report of Chicago Visiting Nurse Association.—The eighteenth annual report of this association shows a steady growth in the scope of the organization's work. The total number of patients cared for in 1907 was 14,981, and 99,510 visits were made by the nurses. Employment for 248 persons was obtained and immediate relief was given to 171 poor families. The report recommends the immediate establishment of a children's hospital for contagious diseases in Chicago. The lack of such an institution is pronounced a blot upon the city. Housing reforms that shall make it criminal for a landlord to take rent for an insanitary living place are urged, and an appeal is made to the Chicago City Council to take notice of the present sad condition of poor people suffering from incurable tuberculosis.

St. Joseph's Hospital, Chicago, to be Enlarged.—Two stories are to be added to St. Joseph's Hospital Building, which already is five stories high. The sixth floor is to be devoted entirely to operating, consultation, waiting rooms, and a laboratory. The seventh floor will be arranged for sun-baths, outdoor sleeping, and exercise. A six-story annex building will be erected on the lot lying just north of the present building. It will be of fireproof construction, with all the latest scientific hospital equipment, and providing every facility for the care and comfort of the patients. Dr. John B. Murphy has been chosen as surgeon-in-chief in succession to the late Dr. Nicholas Senn.

Bequest to Philadelphia Hospital.—By the will of William B. Scott, of Bryn Mawr, Pa., the sum of $25,000 is bequeathed to St. Christopher's Hospital for Children, Philadelphia, for a permanent fund. In the event of the death without issue of two sons for whom a trust fund is created, the remainder of the estate is to be distributed as follows: Children's Seashore Home at Atlantic City, $25,000; Bryn Mawr Hospital, $25,000, and the residue for St. Christopher's Hospital.

Quarantine Against Cuba.—The Marine Hospital service at Washington has announced that after April 1 a quarantine will be enforced against Cuba. This order has occasioned much astonishment and dissatisfaction in the island, as it is alleged that the last yellow fever patient was discharged from the hospital on February 28 and the last infection, that of an American soldier at Santa Clara, was reported on February 21.

Smallpox on Ocean Liner.—The *Graf Waldersee* arrived last Saturday from Hamburg with a smallpox patient in the steerage. The 200 cabin passengers were detained on board for some hours while the vessel was being fumigated before being allowed to dock, and 197 of the 400 steerage passengers who had been exposed were removed to Hoffman Island for observation.

Oxalic Acid Poisoning.—A druggist of Astoria, Queens, has been held by the coroner as being responsible for the death of a woman who died of oxalic acid poisoning after having taken a quantity of what it is alleged was sold as Carlsbad salts. It was shown that in the store the bottles containing oxalic acid and Carlsbad salts were properly marked and were kept on shelves eight feet apart, but the verdict of the jury was criminal carelessness.

Epidemic of Food Poisoning.—Several hundred residents of Upper Sandusky, O., were made ill last week as the result of the consumption of the refreshments served at a church social.

Milk Station for Tompkins Park.—Plans for a model milk station for Tompkins Park have been approved by the Municipal Art Commission, and the Park Commissioner has advertised for bids for the erection of the building, which is to be used for the distribution of pasteurized milk supplied by Mr. Nathan Straus. The new building will be kept open the year around and is to have a room where sick babies may be cared for.

New Postal Regulation.—There has been incorporated in the Post Office Appropriation bill a provision prohibiting the transmission through the mails of intoxicating liquors, cocaine, and its derivatives.

Crippled by Roentgen-Ray Injuries.—Dr. Hall-Edwards, of Birmingham, one of England's first *x*-ray workers, has been obliged to have his left arm amputated on account of intractable dermatitis. His

right hand is also affected, though to a less extent, but he has expressed his intention of resuming his work as soon as he recovers from his present illness.

New Rule Concerning Schoolboy Athletics.—The Committee on Elementary Games of the Board of Education has adopted a rule requiring boys desiring to compete in any athletic contest under the auspices of the Public Schools Athletic League to produce certificates from their physicians to the effect that they are physically fit to take part in such sports.

Gallstone Statistics Desired.—Dr. Hans Kehr, of Halberstadt, Germany, has been commissioned to deliver a report on gallstone surgery before the International Surgical Congress, to be held in Brussels in September of this year, and desires to present the statistics of other surgeons as well as his own. He asks for figures under three headings—pure gallstone cases, complicated curable cases, and complicated incurable cases, including sex, mortality and other results. The views of operators in regard to early operations, technique, etc., are also desired.

Statistics of the Matas Operation for Aneurysm.—Dr. R. Matas, 2,255 St. Charles avenue, New Orleans, La., writes that he is compiling the statistics of operations for the radical cure of aneurysm by the intrasaccular method (endoaneurysmorrhaphy) and will be obliged to all who have had experience with this operation for a brief report of their cases.

Old Age Pension Bill.—A bill under consideration by the Assembly Ways and Means Committee at Albany provides for a pension of $144 a year for all persons over sixty years of age who are incapacitated and have no income. The conditions are that they have lived in the State twenty-five years, have not been convicted of a crime, have never deserted their wives, and have supported their children up to the age of 14.

Another Centenarian.—Mrs. Rheua Miller of Mount Vernon, N. Y., who died on March 9, at the age of one hundred and one years, had seventy-five direct descendants.

German Surgical Congress.—The Thirty-seventh annual Congress of the German Surgical Society will be held in Berlin April 21 to 24, under the presidency of Professor von Eiselsberg, of the University of Vienna.

Düsseldorf Post-graduate Medical School.—Professor Witzel, president of the new Post-graduate Medical School of Düsseldorf, Germany, announces that foreign physicians are permitted to study at this institution without payment other than the registration fee of about a dollar. In addition to opportunities for work all the year around, a special two weeks' course is given, beginning May 4, and another of four weeks, beginning September 28.

Professor Reginald H. Fitz, of the Harvard Medical School, has resigned, owing to his retirement from active work on account of advancing years.

Chicopee Medical and Surgical Society.—An organization with this title was formed in Springfield, Mass., on March 3, with the following officers: *President,* Dr. F. F. Parker; *Vice-President,* Dr. J. O. Beauchamp; *Secretary,* Dr. Warren; *Treasurer,* Dr. W. S. O'Brien.

Hamline University Medical School.—The Medical School of Hamline University has been merged with that of the University of Minnesota, and after the present college year the Hamline Medical Department will go out of existence.

Genitourinary Clinic.—There are several vacancies on the staff of the Genitourinary section at the House of Relief (Hudson Street Hospital), 67 Hudson street, which meets Tuesday and Friday nights, from 8 until 10 o'clock. Any one interested is invited to apply to Dr. Victor C. Pedersen, 45 West Ninth street.

American Society of Tropical Medicine.—The fifth annual meeting of this organization will be held at the Johns Hopkins Hospital, Baltimore, on Saturday, March 28, 1908. The president is Dr. James M. Anders, of Philadelphia, and the secretary Dr. John M. Swan, Philadelphia Polyclinic, Philadelphia.

The Jewish Hospital, Brooklyn.—Dr. Adolph Bonner, formerly of Manhattan, has been appointed adjunct gynecologist to this institution.

Southwestern Iowa Medical Association.—At the annual meeting of this organization held in Creston on February 21 the following were elected as officers for the ensuing year: *President,* Dr. D. C. Brockman, of Ottumwa; *Vice-President,* Dr. Culverson, of Greenfield; *Secretary,* Dr. J. W. Reynolds, of Creston; *Treasurer,* Dr. J. P. Claybaugh, of Creston.

The Late Dr. D. B. St. John Roosa.—At a meeting of the Board of Directors and of the Faculty of the New York Post-Graduate Medical School and Hospital, held on Friday, March 13, 1908,

It was unanimously resolved: That these Boards have learned with great sorrow of the sudden death, on the 8th inst., of their beloved President, Daniel Bennett St. John Roosa, M.A., M.D., LL.D., stricken in the midst of active usefulness, and thus removed from the field of work, which, principally, he originated, established, and for twenty-six years controlled with high-minded principle and energetic devotion.

These Boards, while recognizing the inscrutable wisdom of Almighty God, deplore the loss of a noble man, a faithful friend, a loyal leader, and stanch advocate of the highest and best which each man can give to his profession for the service and benefit of his kind.

These Boards wish further to convey to the grieved widow of our deceased President the expression of their earnest sympathy in her bereavement and their heartfelt appreciation of his eminent services to the Post-Graduate Medical School and Hospital, and of his love and loyalty to each and every member of these Boards.

The following minute was adopted at a regular meeting of the Alumni Association of the New York Post-Graduate Hospital, held Tuesday evening, March 10, 1908:

We meet to-night under the shadow of a great affliction, so sudden, so unexpected, that we have not yet realized how great it is. It will not be easy to fill the position Dr. Roosa's death has left vacant. It probably never will be filled. The work will continue. The Medical School his mind conceived has become an established fact, an integral part of the educational system of the State, while the Hospital he founded and over whose destinies he has presided for the past twenty-five years has become an important factor in the charitable work of New York. No one else occupying the position of President will ever be able to hold all those connected with the institution to their duties through sheer loyalty to the President. This Dr. Roosa has done most successfully, binding all together in a determination to carry on the work of our institution, no matter

what disappointments were met, no matter what obstacles were put in the way, simply because he wanted it—not for himself, but to attain the great object that he had in view.

Dr. Roosa was a strong man, a man of broad education and culture, and his great success as a teacher, as an administrator, as a practitioner of his specialty, came from the force of his intellect and the power he had of presenting facts clearly and cogently. This made him a natural orator and led him to take an interest in affairs outside of medicine. He was a national man, a cosmopolitan man.

He will ever be remembered as the founder of systematized post-graduate instruction for medical men. His was the original conception of the idea which has since been copied throughout the world.

We who have served on the House Staff of the New York Post-Graduate Hospital during the past twenty-five years feel his loss the more keenly because we were made to feel throughout the years of our associatioin with him that he was especially interested in our welfare, not only during our service in the hospital, but during after life. We have all felt his kindly sympathy, and we will all miss the cordial tone with which he used to meet us and inquire of our successes or sympathize with our failures.

Of him we cannot speak as we would. It is said of Sir Christopher Wren, the architect of St. Paul's Cathedral, London, that he did more to beautify the city than all the architects of a hundred years. He lies in a vault in St. Paul's, and above his sleeping dust is a simple slab bearing this inscription: "Here lies Sir Christopher Wren, architect. Would you see his monument? Then look about you." So Dr. Roosa has built his monument in the New York Post-Graduate Medical School and Hospital, and in every other institution the world over devoted exclusively to the systematic instruction of graduates in medicine. He has put his time, his energy, his brain, his heart, *himself* into the great work. The powers thus set in motion for the uplifting and education of the medical profession and the amelioration of the ills of suffering humanity are as far-reaching and immeasurable as eternity.

We thank God that Dr. Roosa lived. We thank God that we have had our medical training under the influence of his precept and example.

To Mrs. Roosa and his family we offer not the perfunctory sympathy of a Medical Society, but the sympathy of those who loved, admired, and reverenced him. His memory will live with us as long as any of us may survive.

For the Association: Franklin A. Dorman, Edward W. Peterson, Douglass W. Cairns, Samuel Lloyd, Chairman.

Obituary Notes.—Dr. A. Campbell White, formerly of this city, died in Providence, R. I., on March 1, at the age of thirty-nine years. Dr. White was born in Providence, was graduated from the College of Physicians and Surgeons of New York in 1891 and served in the Charity and Willard Parker Hospitals. For a number of years he was connected with the Health Department as diagnostician. Ill health compelled him to give up active work a year ago, but he had made plans for an early return to practice in this city.

Dr. Elmer W. Mitchell, of Fall River, Mass., died on March 7, at the age of thirty-five years. He was a native of Fall River and served in the Philippines during the Spanish War. He then entered the Jefferson Medical College and was graduated with the class of 1905, since which time he had practised in Fall River.

Dr. Addison R. Smith, formerly of Rockland, Me., died in Los Angeles on March 6, at the age of forty years. He was born in Williston, Md., and was graduated from Bowdoin and then from Dartmouth Medical School in 1901. He practised for a time in Rockland and then moved to Reno, Nevada, but ill health compelled him to give up work and go to Los Angeles.

Dr. W. S. Bryan, of Cambridge, Ill., died on March 5, of pneumonia, at the age of fifty years. He had long been a prominent physician of Henry County.

Dr. Hal C. Wyman, of Detroit, Mich., died on March 9, at the age of fifty-six years. He was born in Anderson, Ind., and was graduated from the Medical School of the University of Michigan in 1873.

Dr. Jas. W. Dalbey, of Cedar Rapids, Ia., died suddenly in Springfield, Ill., at the age of forty-five years. He was a graduate of the New York University Medical College in the class of 1888, and had practised for many years in Cedar Rapids.

Dr. W. W. Doxey of Nashville, Tenn., died on February 23 at the age of seventy-five years. Dr. Doxey was born in Hendersonville and had practised in Nashville for nearly forty years.

Dr. Maurice M. Dodge of Tacoma died on February 22 at the age of sixty-six years. He was a graduate of Northwestern University and served as surgeon of the Fortieth Wisconsin infantry during the Civil War.

Dr. Lewis Carpenter of San Francisco died on February 20 after a short illness. He was a native of Indiana and was graduated from Missouri Medical College in 1872. He practised for several years in Illinois and later in Texas, in 1887 removing to California.

Dr. Wm. H. Giberson was killed by a railroad train on February 29. He was forty years old and was graduated from Jefferson Medical College in the class of 1896.

Dr. David Maclay died of paralysis at Chambersburg, Pa., on March 3, at the age of fifty-six years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1875. He was a son of Dr. Chas. Maclay of Revolutionary stock. He was treasurer of Franklin County from 1897 to 1900, Representative in the Pennsylvania Legislature in 1802, and postmaster since 1905.

Dr. E. D. Woodhull of Monroe, N. Y., died in St. Augustine, Fla., on March 6 at the age of forty-five years. He was operated on for appendicitis in January and went South to recuperate.

Dr. Charles W. Eaton of Des Moines died on February 27 at the age of fifty-three years after a short illness. He was graduated from the Homeopathic College of New York and the Hahnemann Medical College of Chicago. He was a native of Lancaster, Wis., but for many years had practised in Des Moines, and at the time of his death was director of the medical department of the Des Moines Life Insurance Company.

Dr. T. Bailey Bartlett of Clarksburg, W. Va., died on February 25 at the age of seventy-two years. He was a native of West Virginia and had practised in Clarksburg and vicinity for many years.

Dr. A. F. Ferguson of Lansing, Mich., died on February 23 at the age of sixty years. He had occupied numerous professional and public positions and from 1889 to 1891 was a member of the Legislature.

Correspondence.

TO FURTHER THE SCIENTIFIC STUDY OF ALCOHOLISM.

To the Editor of the Medical Record:

Sir:—During the year 1907 over 200 papers, lectures, and pamphlets were published in Europe and America, presenting different phases of alcoholism and inebriety, purely from a scientific point of view. Many of the authors complain that these papers were not widely read and were practically lost, because they did not reach medical men interested in the subject. The Federation Bureau of this country, organized nearly two years ago for the purpose of collecting and disseminating all facts concerning the alcoholic problem, in connection with the International Bureau in Europe having the same purpose, proposes to secure a list of medical men and scientists interested in the scientific study of the alcoholic problem. This list is to be made available for authors and students who write on this subject, and who wish to address a special audience of physicians, not only to increase their interests, but to stimulate further studies of the subject. Such a list will enable the bureau to extend its work of accumulating facts from the most reliable sources, and keep both authors and readers in close touch with all that is done. This is a practical effort to group and concentrate the experience and observation of medical men, and make them acquainted with what is being done in the scientific study of the alcoholic phenomena. All physicians who are interested in the scientific literature, research work, and studies of this subject by medical men at home and abroad are urged to send their names and addresses for registration and also to receive copies and abstracts from authors and persons who may wish to have their work read and examined by interested parties. As chairman of the board of directors of the Federation Bureau, I urgently request every physician interested in this subject to send me not only his own name, but lists of reputable physicians who would care to receive some of this most important literature coming from the press, and hear what is said in the scientific world concerning this problem.

T. D. Crothers, M.D.

Hartford, Conn.

STUDY OF CLINICAL CASES BY COMMITTEES.

To the Editor of the Medical Record:

Sir:—At the meetings of the London Clinical Society they have a custom which it might be advantageous for medical bodies in this country to adopt, namely, to refer obscure cases to a committee, on which the exhibitor of the patient serves, for investigation and subsequent report. This committee might be made up of members of different sections, and would certainly add to the interest and instructiveness of clinical meetings, where obscure cases are often presented for diagnosis. A. L. Gnichtel, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HEALTHY TYPHOID CARRIERS—TUBERCULOSIS OF KIDNEY, LETTSOMIAN LECTURES—TUBERCULIN T. R. PER OS FOR PHTHISIS—HARVEY'S PRELECTIONES—DAMAGES FOR "NEGLIGENCE" BY A QUACK—BIER'S METHOD—OBITUARY.

London, February 28, 1908

A very important report has been issued by the Home Office in reference to the spread of typhoid. An outbreak at a certified inebriate reformatory was the subject of careful investigation. The first case was in September, 1906, and between then and November, 1907, there were 26 cases, 2 fatal. Dr. Branthwaite, inspector under the Inebriates Act, consulted Dr. Davies, Medical Officer of Health for Bristol, and other medical men, who met at the institution, and it was agreed that every necessary precaution had been taken. But cases continued to occur, with no definite indication of the cause, except that milk seemed more likely than other food. A protective cordon was therefore drawn around the milk from source to distribution. Still cases occurred. The question of a healthy carrier was next investigated and it was found that the dairywoman had had an attack of typhoid fever six years before coming to the institution. The epidemic began after her admission to kitchen work, where it was possible if in an infective state, she might contaminate in some degree the food and milk. Later, when she had only dairy work assigned to her, the epidemic was more virulent. Close inquiry disclosed that she was still in a "highly infective state." She had been removed from the dairy on suspicion when the epidemic ceased. Dr. Branthwaite, in the report, says that whatever else may be deduced from this investigation, it is fairly obvious that persons who have had typhoid should be subjected to careful investigation before holding appointments involving the handling or distribution of food. He further suggests that it is extremely important to discover whether a typhoid "carrier" can in any way be rendered non-infective or whether "chronic carriers" will remain so throughout their lives. In either contingency he thinks the "notification and registration of such persons seems to be indicated until freedom from infection can be guaranteed." Whatever may be thought of this proposal, this investigation will confirm the importance of practitioners bearing in mind the possibility of bacilli carriers being in apparently good health.

This year's Lettsomian lectures have been delivered by Mr. Charters Symonds of Guy's Hospital, who devoted them to tuberculosis of the kidneys. He availed himself of charts, lantern slides, drawings, and specimens, in illustration of several points. He called attention at the outset to the importance of early symptoms, especially to renal colic, and related a typical case of a young lady of twenty who had had three attacks with long intervals between, the case being thought to be due to calculus. Tubercle bacilli were found and the cystoscope showed tuberculosis of the bladder around the right ureter, with swelling of the orifice. The kidney was removed and showed old disease and fresh tubercle. Under tuberculin treatment recovery took place. In another case, a man of forty-six, two attacks of colic had occurred, no calculus was found, and the urine was therefore examined for bacilli. Numbers were present. The cystoscope showed prolapse and edema of the right ureteric orifice. The right kidney was removed and showed old cicatricial tissue and contraction, with recent miliary tubercle. Vesical irritation, from which the patient had suffered, disappeared after the operation. This symptom, said the lecturer, may be the only early indication of renal or tuberculous mischief, as also may urethral irritation, and he related cases in proof, one in which vesical irritation was the only trouble for twelve months. On cystoscopic examination the right ureteric orifice was found swollen, with white elevations. The kidney was removed with the ureter. Rapid recovery followed. The kidney showed extensive tuberculous disease. Other cases were equally successful and well enforced the lecturer's insistence on the necessity of examining the urine in cases of renal colic, especially in young patients; the importance of renal and vesical irritation as early indications of kidney diseases, especially tuberculosis, and, further, that this should be suspected when the amount of albumin in the urine is greater than can be explained by the pus.

In his second lecture Mr. Symonds returned to this point and said the albumin is generally more abundant than can be accounted for by pus, and, moreover, may be present without other symptoms, not only when the ureter is shut off, but also when it is patent. Special attention was called to the fact that, as miliary tuberculosis is painless, extensive destruction may occur without symptoms, so that an examination for bacilli should be made in all cases of unexplained albuminuria. Hematuria was named as an early symptom and a case quoted as probable, but renal infection could not be demonstrated and the patient recovered under tuberculin treatment. The lecturer said that routine examination of the urine in anemia and ill health would often reveal tuberculosis of the kidney, and there was no reason why they should not recover. Indeed, he was inclined to think that many cases of albuminuria that did recover were of tuberculous origin. He thought the ureteric orifice did not show characteristic changes until the ureter itself was infected. Infection of the bladder was generally late. It is curious how tolerant this organ is to tuberculous pus; in some of the cases it must have entered the bladder for two years or more. Immediate nephrectomy when one kidney was found to be infected did not seem necessary, as proved by some of the cases, and the lecturer thought postponement justifiable when the bacilli were few, irritation slight, and bladder and ureteric orifice normal, but when this orifice has become affected nephrectomy should be performed. Whether slight infection of the other kidney contraindicated operation was a question turning upon the distress occasioned by the obviously affected organ, and the curability of renal tuberculosis. When the distress was great and affecting the health, Mr. Symonds thought operation should be done as tending to improve the general health and promote the recovery of the less diseased kid-

ney. Whether the ureter should be removed at the same time depended a good deal on the state of the patient. Mr. Symonds was in favor of removal if the patient seemed able to bear the additional strain, but as recovery may take place when the ureter is left, he would not advise undue risk. The advantage of a preliminary nephrotomy was shown by a case in which this quite relieved the general infection and the complete operation was done later. Preliminary incision gives an indication of the amount of renal tissue left. The urine can then be collected from the bladder and the secreting capacity of the other kidney ascertained. On the whole, nephrectomy is not negatived by vesical tubercle nor by slight miliary tubercle of the opposite kidney.

A case was shown in the Clinical Section of the Royal Society of Medicine which is not without interest in reference to Mr. Symonds' remarks on tuberculin treatment. It was a case of consumption shown by Dr. Arthur Latham, who had treated it by tuberculin T. R. and horse serum administered by the mouth on six or seven occasions during a couple of months. For the last month he said the temperature had been normal or subnormal, the sputum had diminished from 6 ounces to 1 ounce per diem, and the patient had gained seven pounds in weight. He had fourteen other cases undergoing this treatment. A member remarked that the treatment suggested a consideration of what would be the effect of feeding on the meat of tuberculous animals.

Osteoarthritis seems sometimes to start with injury to a joint and it would appear that such injury need not be recent, for at the Clinical Section Mr. Godlee showed two men, illustrating a very late onset if the injury was a determining factor. One had a fracture of the lower end of the right humerus twenty-one years ago and now has arthritis of that elbow, but of no other joint. The other had had dislocation of the patella long before osteoarthritis of that knee. Another instance was mentioned by Mr. Openshaw, who agreed as to the connection between the injury and the later disease. Dr. Poynton remarked that organisms introduced by intravenous injections may settle down in a single joint and previous injury to such joint may diminish its resistance. Dr. Garrod remarked that the first attack of gout often takes place in a joint that has been injured long before.

An interesting literary event is the publication by the Royal College of Physicians of Harvey's "Prelectiones Anatomicæ Universalis" from the MS. of the original lectures delivered before the college in and after 1616, including his earliest observations on the heart and circulation. The volume is edited, with an autotype reproduction of the original, by a committee of the college, who state in a preface that the MS. is to be regarded with veneration as one of the most precious of the archives of English science, and as showing how Harvey had begun to penetrate the difficulty of explaining the motion of the blood, and how long his active mind was willing to enlarge and confirm its first thoughts before he gave final expression to them and published his splendid discovery of the circulation, matured and completed by twelve years of observation and meditation.

The Pharmaceutical Society—rather late in the day—has summoned the vendor of the "asthma specific" for selling it without a poison label, and a fine of £5 and costs has been inflicted. If the society did its duty in this respect some check might be put on quackery. But the pharmacists are the chief vendors of "proprietary medicines." Curiously, in this case, it seems that the sales were more largely made direct to the public than through the druggists.

A man trading as "Dr. Hall's Hygienic Company" has been sued by a woman for negligence in continuing to dose her for months for cancer of the breast, preventing her from applying to a surgeon until her case was hopeless. The jury awarded her £600.

Dr. W. Ewart takes exception in the *Lancet* to Dr. Allen's suggestion in your columns (MEDICAL RECORD, January 4), to adopt the formidable Teutonism, "Staungs-hyperämie" for Bier's method. Dr. Ewart thinks our own language supplies a better term, viz., that "used some thirty years ago by Hugh Owen Thomas, the pioneer of the method in this country." The phrase is "dammed circulation," quite comparable with that of "interrupted circulation," which has obtained a place for an opposite vessel-compressing method.

Dr. Conolly Norman, medical superintendent of the Richmond Lunatic Asylum, died suddenly on Sunday in his fifty-fifth year. He had been connected with the asylum above twenty years. He had a weak heart, and had lately suffered from bronchitis following influenza. When taking a short walk he fell near his home, was carried in immediately, but rapidly succumbed. The asylum was practically reorganized during Dr. Norman's tenure and he was recognized as among the very foremost experts and administrators of the time. He was joint editor of the *Journal of Mental Science* and wrote in Luke's *Psychological Journal* and Allbutt's *System*, besides contributing to periodicals. Last year the University of Dublin conferred its honorary degree upon him in recognition of his work.

The death of Dr. H. R. Silvester in his eightieth year is announced. He was the proposer of the Silvester method of resuscitating the apparently drowned. He was a London graduate, M.B., 1853; M.D., 1855. He received the Fothergill gold medal of the value of 50 guineas from the Royal Humane Society in 1883 on their adoption of his method.

Dr. J. H. Pigeon of Bristol died on the 19th inst. at the R. Infirmary, to which he was taken the previous day in a delirious state from pneumonia supervening on influenza. He was actively engaged in practice up to two or three days before his seizure.

Dr. Richard Gorst, for many years a leading practitioner in Lancashire, has died in the eighty-fifth year of his age. He qualified in 1848 and only retired two or three years ago.

Dr. R. S. W. Wilson of New Church was found dead in his bed on the 18th inst. He was in his usual health when he retired on the evening before and had attended to his practice up to then. He was fifty-four years old and qualified in 1879 with the Edinburgh double diploma.

OUR LETTER FROM COPENHAGEN.

(From Our Own Correspondent.)

DETECTION OF TUBERCLE BACILLI—VICTORY OF MEDICAL MEN OVER THE COPENHAGEN MUNICIPALITY—GASTROSCOPY AND GASTRODIAPHANOSCOPY.

COPENHAGEN, February 22, 1908

At a recent meeting of the Medical Society of Copenhagen Drs. Ellermann and Erlander reported on their researches on a new method for the detection of tubercle bacilla in substances in which they are present only in a small number, and perhaps very irregularly distributed. A critical comparative examination of the methods hitherto in use for a similar purpose has taught the investigators that their procedure surpasses all former ones, giving, as it does, an increase of the relative number of bacilli up to twenty times the original number. When examining sputum one has (1) to mix carefully 20 c.c. of the sputum with 10 c.c. of a 0.6 per cent. solution of carbonate of sodium and place the mixture in the thermostat for twenty-four hours at 37° C.: (2) centrifugation; (3) to the precipitate add four parts of a 0.25 per cent. solution of NaOH, mix carefully and boil half a minute; (4) centrifugation. The first stages of the proceeding are a little different, when urine has to be examined. The clear liquid is first poured off the sediment, which is subsequently centrifugated. To the centrifugated precipitate add four parts of a 0.25 per cent. solution of carbonate of sodium, and .25 to 50 centigrams of pancreatin. Place the mixture for twenty-four hours in the incubator at 37° C. and continue by proceeding as above, sub. (2) and (4).

I am happy to be able to record a great victory won by the profession in Denmark in a struggle with our largest municipality, Copenhagen. As I wrote you last summer, the profession there united into one compact body, the General Danish Medical Association, which numbers all the 1,600 to 1,700 medical men in Denmark amongst its members. One of the subdivisions of the association is the Association of Junior Medical Men, consisting of the post-graduates not yet in actual practice. Their number is a comparatively large one, as most of them only begin to practise six or seven years after the final examination, the intervening time being spent in studies at different hospitals. The Danish hospitals are not charitable institutions in the same sense as most of the American and English hospitals. Our hospitals are not supported by private subscriptions, but the expenses of running them are defrayed by the municipalities out of the rates, or by the crown out of the taxes. Another difference is that the vast majority of the patients pay for their stay and treatment in the hospitals, though, of course, only a fraction of the real cost. Thus the municipality of Copenhagen, with a population of 440,000, maintains ten hospitals, with a total of 2,900 beds, plus a lunatic asylum of 1,400 beds; the ten hospitals alone have a yearly budget amounting to $900,000, each patient costing the municipality about $1 a day, while he only pays 15 cents daily. As is seen, the hospitals are here run in a more businesslike way, and that is one of the reasons why we do not have an institution like the honorary hospital staff of the Eng-

lish-speaking countries. Here all members of the staff, young and old, are salaried, as are also, of course, the resident house surgeons and physicians. As, however, the salary has hitherto been sadly inadequate, the Association of Junior Medical Men began to work for a raising of the salary, and the Town Council of Copenhagen had nearly granted the very modest wishes of the association, when in the decisive meeting of the Council a colleague was found willing to speak against them, with the result that the requested augmentation of the salaries was only partly granted. The Association of Junior Medical Men then at once invited its own members, and with the support of the General Medical Association, all Danish doctors, to abstain from applying for appointments in the municipal hospitals of Copenhagen. The pressure thus brought to bear on the Town Council was very strong, as many appointments would soon become vacant. After a very short time the Councilmen therefore thought fit to make a virtue of necessity, and granted, though with a bad grace, the request which they had four weeks before denied so sternly. This victory is not only important, because it enables the junior medical men to subsist during their postgraduate studies without running into debt, but its chief importance is to be found in the fact that our richest municipality has had to give way before the united profession, and that no outsiders were found amongst the colleagues.

At the last meeting of the Copenhagen Medical Society Professor Thorkild Rovsing demonstrated a new and original method of gastroscopy and gastrodiaphanoscopy. Even when during a laparotomy the operator has the stomach in his hands, it is often impossible for him to tell whether or not there is a new growth or an ulcer in its wall. In these dubious cases Rovsing introduces through a little slit in the anterior wall of the stomach an optical instrument, built on the same principle as the cystoscope, but larger, and closes the stomach wall air-tight round the shaft of the instrument by means of a circular suture. Air is then blown into the stomach through a tube in the shaft of the instrument, so that the stomach expands, and, when light is turned on, presents itself as a luminous globe, on which the vessels, nay, even the different layers of the musculature, may be observed. A new growth appears as a dark spot on the luminous globe, while an ulcer very often causes the appearance of a ring with a darker periphery (the thickened walls of the ulcer). This gastrodiaphanoscopy may be followed by gastroscopy through the optical apparatus of the instrument. The picture thus obtained of the interior of the stomach is exceedingly clear and instructive. The method, as simple as it is efficient, is sure to prove of great helpfulness to all surgeons operating on dubious stomach cases.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CHOLERA IN MANILA—RESTRICTION IN THE SALE OF COCAINE.

MANILA, P. I., January 29, 1908.

DURING the closing days of the old year, and during the first week of the new year, the cholera outlook of the city of Manila assumed a rather serious aspect. The cholera increased from day to day, until on January 6, 17 cases per day were reached. The increase during the latter part of December can probably be ascribed to the fact that there was a large influx of visitors into the city of Manila to spend Christmas. Many of these people came from infected places, and were in the incubation period of the disease when they arrived here; and it seems quite probable that some of the stools from more virulent cases fell into the hands of the Chinese market gardeners, who used them for fertilizing purposes. The thus infected products were sold in the markets, and in a number of cases the disease can almost with certainty be ascribed to this cause. It is probably not known in the United States that the Chinese gardeners make a solution of human feces with water, and use the same for sprinkling purposes, in order to drive away the vermin which has such a destructive effect upon garden products in the tropics. From the foregoing, it will be seen that a head of cabbage, for instance, would become infected from its very center to its outside as it gradually forms, and on that account be rendered exceptionally dangerous.

January 3 the disease made its appearance in the Mariquina valley, which is the watershed for the city of Manila. During the first week of the outbreak, of the 45 cases reported, there were 43 deaths. The Governor-General, upon the request of the Bureau of Health, made application to General Wood, the Commanding General of the forces in the Philippines, for the detail of sufficient troops properly to patrol the Mariquina river and guard it against infection from cholera. Fortunately, the disease first made its appearance in the town of Mariquina proper, where a pail system is maintained, and where there is less likelihood of fecal discharges finding their way into the water. Energetic measures were made to stamp out the scourge in that locality, and these efforts were rewarded with considerable success. During the week that followed, only a few additional cases occurred, and during the past ten days there have been no further cases in the valley.

An investigation is now being made of the sewers of the city of Manila, and a number of them have been found to be cholera infected. It is quite probable that the flies, roaches, and other vermin that infest these places carry the cholera organisms upon their feet and also by means of their fecal discharges infect easily contaminated food stuffs.

The sale of all vegetables which are likely to be eaten raw has been prohibited. Apparently the disease is coming under control rapidly in the city of Manila. During the past week from one to three cases only per day have been reported. Cases have occurred in Manila as follows:

	Cases.	Deaths.
January 1 to 8	42	32
January 8 to 15	72	50
January 15 to 22	41	27
January 22 to 29	23	13
Totals	178	122

Cholera in the Philippine Islands, and more particularly in Manila, presents much the same problem as does typhoid fever in the United States, with this difference, viz., the disease is much more likely to assume epidemic form with a mortality of 60 to 80 per cent. as against 5 to 20 per cent. for typhoid fever. The same measures, however, which are necessary to eradicate typhoid fever will have to be put into effect here before the complete disappearance of this disease can be hoped for.

The installation of the new sewer system and the city water supply from an uninhabited watershed are improvements which are now three-fourths completed, and should do much to assist in solving this problem.

Under Act No. 1761, passed by the Commission October 10, 1907, the use of cocaine has been placed under severe restrictions. The law provides in brief that any person who shall inhale, snuff, chew, swallow, inject, or otherwise use or permit to be used in or on his body any cocaine, alpha or beta eucaine, or any derivative or preparation of such drugs or substances, except upon the prescription of a duly licensed and practicing physician, shall be subjected to a fine of not to exceed $10,000, or by imprisonment not to exceed five years, or both, in the discretion of the court. The possession of any hypodermic syringe, apparatus, instrument or paraphernalia for using cocaine, alpha or beta eucaine, or any preparation thereof, is deemed to be prima facie evidence that the person in possession of such implements used some of such prohibited drugs without the prescription of a duly licensed and practicing physician unless the prescription can actually be produced by such person.

After March 1, any cocaine, alpha, or beta eucaine, which is in the possession or under the control of an unauthorized person, shall be seized and forfeited to the Insular Government. The purpose of this law was to prevent the opium habitués from becoming cocaine users, many of whom had already taken to cocaine on account of the restrictions placed upon the sale of opium.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 5, 1908.

The Surgical Treatment of Various Conditions as Influenced by Pregnancy.—M. Storer protests against the currently accepted theory that pregnancy contraindicates all surgical intervention. He has made a careful study of the literature bearing on the point, and finds abundant evidence that nearly all operations have no influence on the course of pregnancy, except to favor its continuance, provided that they are not followed by a septic process which by reason of continued high temperature may cause the death of the fetus and abortion. Much of the information given is in tabular form and cannot be abstracted. Before con-

sidering any operation, we must ask ourselves what effect the condition if left alone will have upon the health of the woman or upon pregnancy and labor, and defer interference in cases where it can be done. In operations of election, it is undoubtedly best to operate at the time of least uterine excitability, *i.e.* to avoid the times when the woman would be menstruating if not pregnant, and also, if there is a history of intermenstrual dysmenorrhea, the few days midway between the time of the periods should be avoided. It does not seem proven that there is greater reflex excitability at any one month than at others. We must consider whether in the given case the life of the child is too important to run even the slightest risk of abortion, *e.g.* whether the woman has other children or is likely to be pregnant again. On the other hand, a wise radicalism may be the truest conservatism. A myomectomy on a woman who has aborted a number of times may enable her to go to term. The author enumerates the special dangers which exist in each period of pregnancy and discusses preferable modes of operating in various clinical emergencies.

New York Medical Journal, March 7, 1908.

A Study of the Prostate with Reference to the Curability of Gonorrhea.—A. L. Wolbarst presents the following conclusions: (1) The so called "incurable" and "recurrent" cases of gonorrhea are those in which the gonococci remain latent in the prostate and annexa. (2) Every case of chronic gonorrhea in the male should be thoroughly examined for gonococci in the prostate and adnexa. (3) The morning urine passed by the patient may or may not contain gonococci; the massaged urine passed immediately after, or, better still, if it can be obtained, the expressed secretion of the prostate, will most always give a positive finding. (4) The urine passed by the patient may be clear and sparkling; yet the massaged urine may be full of pus, and epithelia, which are loaded with gonococci. (5) There is no direct relationship between the urine clearing up and the disappearance of gonococci from the prostate. (6) Five examinations of the massaged urine may give a negative result. The sixth may give a reverse verdict. Here persistence is a cardinal virtue. (7) Before a patient can be declared "cured" and marriage sanctioned, he should be put on the customary tests, and in addition, the massaged prostatic secretion should be examined at weekly intervals until at least six consecutive negative findings result. Thereafter for at least a year, a monthly examination of the same kind should be made, so as to make assurance doubly sure.

Gallstone Disease and Its Surgical Aspect.—T. Hawkes says that gallstones should be removed at an early date from gallbladder or ducts; such infection is treated by drainage of the ducts. At this time the operation is comparatively safe, convalescence is prompt, and cure lasting. Serious complications are liable to arise at any time in patients with chronic gallstone disease. Long journeys, in which efficient surgical aid cannot be secured promptly, are distinctly hazardous. Operations at this time are much more serious, they are often necessarily incomplete, and the outlook for permanent cure is less bright. Cancer is liable to develop at any time at or near the seat of irritation. Operation then is very hazardous and the outlook bad. Medical practitioners should familiarize themselves with the results obtained by the surgeons to-day in the early uncomplicated cases.

Colorimetric Analysis of the Saliva with the Clinical Significance.—B. R. Le Roy enumerates the various tests used in analyzing saliva and reports Fennick as saying that the sulphocyanides bear a relationship to the amount of sulphur in the bile, and that when the latter is diverted from the gastroenteric canal, the former disappear from the saliva. The sulphocyanides and ammonia in normal saliva are about in equal proportions and in very small amounts. When the sulphocyanides disappear from the saliva we have a condition that needs our careful attention, and if ammonia is increased in quantity we have a grave condition, indeed, to combat; this is an hypoacid condition and accompanies all the graver forms of disease; for instance, this is the state of affairs in all diseases of the nervous system, *i.e.* absence of the sulphocyanides with ammonia present in large quantities, the larger the amounts of the latter the more grave the condition. This is true of epilepsy, paralysis, dementia præcox, and all forms of nervous diseases resulting from lues. And when the author has been able to detect the sulphocyanides in these cases he has always felt sure of a period of improved state of health, and upon the disappearance of the sulphocyanides from the saliva he was just as certain that the old attacks would return. We also have this state of affairs in all forms of fevers, exemplified in its extreme in the typhoid state. Here, too, we will notice the appearance of the sulphocyanides in the saliva in advance of returning health; indeed, this holds good in all cases of recovery from any and all forms of disease. Upon the other hand, when we have an excess of the sulphocyanides in the saliva, giving a deep dark blood red reaction, and it continues so for a space of time, he looks for a lesion in the brain, heart, or in the kidney, and pays special attention to these organs. When we have a hypoacid condition the patient cannot tolerate acids nor iron—that is, these remedies will not agree with the patient; but change the ammonia base to potassium and the patient will ask for acid drinks! Sodium base will cause the same changes to take place in the milder forms of disease.

The Operative Tendencies in Modern Obstetrics.—A. Stein traces the gradual introduction of operative procedures into obstetric practice. He regards vaginal cesarean section as representing a distinct advance and gives a full description of Dührssen's method. Latest statistics show a mortality from it of only 1 per cent., excluding all deaths due to other causes than the operation itself, while abdominal cesarean section has a mortality of from 6 to 8 per cent. Stein then passes on to consider those operations which bring about an enlargement of the birth canal by cutting through some portion of the bony pelvis. Pubiotomy, while not without faults, offers many advantages over symphyseotomy, and is indicated in all cases in which perforation of the living child was hitherto resorted to, especially in cases of flat or generally contracted pelves, in which there is a disproportion between the size of the fetal head and the size of the pelvis. The average mortality after symphyseotomy has been reduced to 8 per cent. Following the newer operation, it is only 4.2 per cent., and if we exclude those cases which were infected before operation only 2.9 per cent. Other operations which are now regarded as perfectly feasible are the removal of large tumors during pregnancy and labor, the resection of pelvic veins, and hysterectomy for septic conditions during the puerperium. The author regards pubiotomy as a risky undertaking for the general practitioner and believes the operation should be done only by the man familiar with pelvimetry, obstetrical diagnosis, and the technical features of the operation, and, above all, a man equal to the task of meeting any of the complications liable to come up during and after the operation.

Journal of the American Medical Association, March 7, 1908.

Acute Articular Rheumatism.—P. K. Brown sums up his conclusions as follows: 1. Diseases with acute joint symptoms resembling each other in the character of the joint involvement and accompanying complications, belong to a definitely infectious group. 2. The nature of the infection is clear in the following group: Group 1. Septicemia, pyemia, puerperal fever, typhoid, pneumonia, epidemic meningitis, influenza, dysentery, gonorrhea. 3. The character of the disorder has been established as definitely infectious in: Group 2. Scarlet fever, smallpox, dengue. 4. An infectious origin is presumed on good analogical evidence in: Group 3. Acute articular rheumatism, acute arthritis deformans, Still's type and the erythema group. 5. When the infectious diseases with acute joint symptoms and known etiology and also those with established identities but still uncertain etiology have been eliminated, another group remains which contains acute articular rheumatism, acute arthritis deformans and the erythematous type of lesions. That specific toxic agents are responsible for these seems not doubtful, and that these agents differ from each other is probable. 6. The final diagnosis of acute articular rheumatism can only be made after Groups 1 and 2 have been excluded, and there are clinical differences clearly separating the diseases in question from the other members of Group 3. 7. There are cases in all groups that can be diagnosed only with the lapse of time, and some which can not at present be differentiated at all.

The Vaccine Treatment of Gonnorrhea in Children.—The result of the opsonic treatment of gonorrheal vulvovaginitis in a small hospital epidemic, involving twelve children of ages ranging from one and one-half to twelve years, is reported by W. J. Butler and J. P. Long. The gonococcus was readily grown on blood serum and blood agar. They found a considerable advantage in using young cultures from six to eight hours old, to avoid trouble from clumping, and consider this an important point in minimizing the difficulties of opsonic work in general. This holds good in the preparation of the vaccine as well as that of the emulsion. The following method of staining was found especially serviceable: After fixing in a bichloride solution and washing, they place the slide in a 2.5 per cent. solution of sulphuric acid for several seconds, until the coloring of the smear fades; it is then washed off in water and stained with an alkaline aqueous solution of methylene blue for one

minute. This makes an excellent slide for counting. The vaccinations were interspaced according to the opsonic index, the normal of which was determined from the average phagocytic count of four healthy boys. Two vaccines were employed; one from a single case of gonorrhea, the other from cultures made from four cases. Both were standardized to 20,000,000 per cubic centimeter. In the more protracted cases a change of vaccine was made from the first of these to the second, with very prompt results in two of the cases, and the authors think it not improbable that a vaccine made from cultures taken from several cases of gonorrhea may in some instances be more effective. In all the twelve cases treated by the opsonic method, except three, the discharge disappeared and smears were negative after a few weeks' treatment. The three exceptions were handicapped by inability to control their disposition; reinfection is suggested as possible. All three cleared up, but a slight discharge has recurred in two of them. In the third, the discharge also recurred, but has since cleaned up and the smears are negative.

Local Arteriosclerosis.—F. Fremont-Smith concludes that arteriosclerosis is often, in its beginnings, a local disease, dependent on acute or chronic infections. Its final outcome depends on the extent of the primary injury to the vessel and the success or failure of natural reparative processes. Arterial hypertonus may sometimes exist independently of arteriosclerosis, and he gives personal observations of such cases as well as testimony from the literature. Its persistence, however, as Hare has shown, may be regarded as a precursor to arteriosclerosis. It may or may not produce, or be associated with causes which produce cardiac vascular phenomena. On the other hand, the arteriosclerosis exists independently of arterial hypertonus as both a local and a general disease, and the absence of hypertension must not be regarded as security from dangers arising from arterial degeneration.

Postpartum Perinephritic Abscess.—J. S. Horsley reports three cases of perinephritic abscess occurring in his practice within the past two years. In all three patients the first symptoms appeared within a few weeks or days after confinement, and in two were preceded by a distinct interval of apparently perfect health. One patient gave a history of slight puerperal infection, but in all three a vaginal examination, made when first seen by Horsley, showed no evidence of inflammation in or about the uterus, ovaries or tubes. It is probable, he thinks, that there was some septic infection during the labor or convalescence that was carried to the kidneys by the lymphatics when their surrounding tissues were in a condition of lessened resistance from the effects of the muscular strain and pressure during parturition. In all three cases, the abscess was on the right side, a fact possibly accounted for by the lower position of the right kidney making its perinephritic tissue more liable to injury from uterine pressure during labor. The diagnosis in these cases is very important, as the symptoms are often vague in the beginning, and the successful management is largely dependent on the promptness of recognition and treatment. Whenever, after an injury or violent muscular exertion, as in parturition, there is tenderness on pressure over the kidney, and the patient on sitting or standing inclines to the tender side, the possibility of perinephritis is at once suggested and the case should be followed and watched for further symptoms. These are given by Horsley; among the earlier ones are spinal stiffness and curvature in an anteroposterior direction, pain on pressure, often deep-seated and paroxysmal, but generally to some extent continuous and rather widely distributed. If in the knee, with stiffness and lameness, it may suggest hip-joint disease. The temperature, even in the earily stages, frequently reaches 103 F., or higher, in weakly individuals the symptoms may be atypical and mask the condition until the increase of size forces the recognition of the abscess. The urine is not often affected in perinephritic abscess following parturition, unless the abscess ruptures into the kidney, which is rare. The treatment consists in evacuating and draining the pus by a lumbar incision, similar to that employed in nephrotomy. It should be done as soon as the diagnosis is made, as delay greatly increases the mortality.

Glandular Fever.—F. W. Terflinger gives an account of an epidemic of glandular fever that occurred among the inmates and employees of the Northern Indiana Hospital for the Insane, in the winter of 1904-5. The notable features of this epidemic were the number of persons attacked (150) and their ages, ranging from eighteen to eighty. Heretofore this disease has been considered a disorder of childhood. He offers the following conclusions: 1. Glandular fever may and does affect adults, and is not a disease of childhood only. 2. Sex, age and occupation have no influence. 3. In adults, complications and sequelæ are rare. 4. The prognosis is favorable.

The Lancet, February 29, 1908.

Acid Intoxication Following the Administration of Chloroform.—The patient of H. Thorp was a boy about four years old, who was circumcised. About two drams of chloroform were given over a period of seven minutes. Immediate sequence was without incident. About fourteen hours later he presented noisy respiration, rapid and feeble pulse, and could not be roused. The lungs were full of moist râles. Vomiting came on and was recurrent. Fifteen hours from the onset of his symptoms the smell of acetone was perceptible in the breath. Urine was secured by catheter. Symptoms continued as above, with slight general twitchings, screaming attacks, apathy, loss of conjunctival reflex, and finally, in spite of all therapeutic measures, death ensued thirty-six hours after the operation and twenty-three hours after the onset of symptoms. The urine contained 8.31 gr. urea per ounce. Reaction for acetone was positive; for diacetic acid doubtful.

Two Cases of Anthrax.—J. S. Clarke reports the cases, the first being that of a farmer with symptoms of some severe constitutional disturbance and a sore on the left forearm about one inch in diameter, with a depressed center and an annular zone of vesicles. The depression was purplish-red, not black. Edema and pain were absent; axillary glands enlarged. Smears were made and bacilli resembling those of anthrax were made. Under chloroform the sore was excised and healed without incident. Culture tests confirmed the diagnosis. The second case was that of a man who had helped the farmer kill a diseased bull four days previously. The animal's viscera presented nothing unusual and were eaten by pigs, who suffered in no evident way. The assistant's local lesion was on the back of the wrist. The pustule was far more typical than was that of the farmer. Constitutional symptoms were wanting, but the axillary glands were enlarged and the wrist was slightly edematous, with some redness about the sore. Excision was done under local anesthesia with ethyl chloride. Healing was without incident.

Pathology and Etiology of Intussusception from the Study of a Thousand Cases.—This analysis is made by D. C. Fitzwilliams, who has drawn his material from various hospital reports and journal articles. His definition and description of the condition follow the conventional lines. We can mention only a few of the many points brought out in the interesting paper. The author contends that ileocecal cases are all of enteric origin, and supports his views by the following arguments: 1. The ileocecal valve is the narrowest part of the intestine; it is in consequence the most unlikely spot for the inner to slide through the returning layer. 2. The ileocecal form of intussusception is so common and the ileocolic form comparatively so rare as to make it unlikely that the extreme end of the ileum should in some cases, for reasons unknown, assume a totally different mechanism of the invagination. For be it remembered that according to the accepted view the ileocecal valve is the starting point of both varieties. 3. Owing to the anatomical arrangement of the layers there is no force present which renders it possible for the inner tube to pass through the returning layer. 4. In an ileocolic intussusception there is no way of excluding the possibility of its having started in the lower end of the ileum and passing through the valve by the same mechanism which operates in all other portions of the alimentary canal. 5. Many instances of enteric intussusceptions are met which, if growth continued as far as the valve, would be indistinguishable from what is now called ileocolic forms. 6. Many intussusceptions have been reported as ileocolic varieties, although there was an ulcer, a polyp, or even a Meckel's diverticulum at the apex, conditions which are well recognized as being the starting point of intussusceptions in the lower portion of the ileum. 7. Ileocolic intussusceptions can, as I have just demonstrated, be easily explained as having taken place by the ordinary mechanism if it is only recognized that they are enteric in origin and have not *started* at the valve. We are, therefore, driven to the conclusion that the so-called ileo-colic form should not be described as a separate variety of intussusception, and this class is accordingly grouped with the enteric cases. Statistics are given as to the point at which the intussusception begins. In the urgency of an operative, and in the limited space of a small incision, determination of this point is often difficult. The spiral twist, which is sometimes found in extensive invagination, and which may be occasionally one of the obstacles preventing reduction, is the direct result of the intussusception traveling in a corkscrew-like manner round the root of the mesentery. Occasionally one may find a retrograde intussusception. In such cases, the lower part of the

bowel is invaginated into the part above. Such cases are commonly seen in the autopsy room, but are rarely met with during life. It is quite certain, however, that they do form during life, and are capable of giving rise to the same acute symptoms as does the descending variety.

British Medical Journal, February 29, 1908.

A Plea for a Neglected Remedy.—Eustace Smith deplores the neglect in these later days of the use of antimony, which he regards as one of the best remedies in catarrhal states of mucous membranes. No other drug approximates its value in bronchial catarrh. Many of the cough mixtures given in the early stages of this malady are constructed on wrong principles. Ammonia, squills, and paregoric in the earlier stages make the cough harder and the chest tighter. In this way a catarrh is driven back into the smaller tubes and in children a bronchitis may be turned into a pneumonia. Such remedies are all right for the later stages. The remedy *par excellence* for the earlier stages is antimony in small and frequent doses, stopping short of its depressing effect. It is well to combine it with a diaphoretic. The antimonial wine is undoubtedly the most convenient form for administration. Definite indications are difficult breathing, incessant and hacking cough, small and feeble pulse. In the early stages of bronchopneumonia, laryngeal stridor, upset stomach (here in small doses). An old-fashioned mixture for gastric pain after meals is one teaspoonful in half a glass of water as soon as the pain begins of a mixture containing one and one-half grains of tartar emetic, one ounce of magnesia, six drams of bicarbonate of soda and five drams of tartaric acid. Antimony is also a valuable hepatic stimulant, and is of service in inflammatory skin conditions, especially acute and chronic eczema.

Scarlatina Associated with Pyrexia in Apparently Healthy Contact Cases.—Personal experience in a recent epidemic is given by B. Thornton. His main contention is that it is very likely that in a community infected with scarlatina, in addition to those who show definite symptoms of the disease, there are others who are affected by the poison to a minor extent, as shown simply by an elevation of temperature; and it may be a useful precaution to take the temperature of contacts, with the view of keeping under special observation those who, though apparently quite well, are suffering from a moderate degree of pyrexia.

Treatment of Experimental Trypanosomiasis.—The results of experimental work by A. Castellani justify the author in presenting the following conclusions: (1) Quinine cacodylate shows a well-marked trypanocide action in monkeys experimentally inoculated with a strain of trypanosome closely resembling *T. evansi*. (2) Mercury perchloride improves the general condition of the inoculated monkeys, and frequently causes the temperature to subside to normal. Given alone, however, its trypanocide action is not very marked. In patients affected with sleeping sickness it would seem from the experiments made by Low and the author in 1903 that mercury perchloride given by intravenous injection induces a fall in the temperature, but the improvement is only temporary. (3) The author suggests that quinine cacodylate alone, or, better, in combination with intravenous injections of perchloride of mercury, should be tried in sleeping sickness, using large doses. If it should be found that quinine cacodylate has a marked trypanocide action also on *T. gambiense*, the advantage of this drug over other preparations would be its powerful action on the malaria parasites. This would be an appreciable advantage, as in the experience of many observers, among whom Low and the author, a large number of sleeping sickness patients are suffering also from chronic malaria. (4) Quinine cacodylate, besides its trypanocide properties and its action on Laveran's parasites, has apparently some action on other protozoa, as, in the author's experience, its use is beneficial in kala-azar and yaws.

Berliner klinische Wochenschrift, February 17 and 24, 1908.

Specific Sera for Plant Albumins.—Gasis discusses the subject of the precipitin reactions and describes observations made by adapting animals to the albumins of various plants. For this purpose rabbits were injected with substances obtained from rye, rice, and beans, by the following process: The various flours were extracted with 10 per cent. salt solution, the salt was then partially removed by dialysis, the resulting precipitate of globulins filtered off, the proteins in solution preciptated with alcohol and dilute acetic acid, and then washed with water, alcohol, and ether. The resulting powder gave the albumose reactions. In adapting the animals 0.05 g. of the substance in 10 c.c. of salt solution was injected subcutaneously, or 0.01 g. in 2 c.c. of salt solution was injected intravenously. It was found that distinctly specific sera were produced and that it was even possible to distinguish in this way between beans of different species. The reactions were more or less pronounced according to the degree of relationship of the plants tested and the differentiation was possible at lower dilutions than is the case in dealing with animal albumins.

The Diagnosis of Gastric Ulcer.—Bönninger has found the following procedure useful as an aid in the diagnosis of gastric ulcer: In the morning, while the stomach is in the fasting condition, it is washed out with 100 c.c. of water, and this fluid is afterward subjected to the usual tests for acidity, mucus, blood, epithelial cells, etc. Then one or two hundred c.c. of 1/10 normal hydrochloric acid is introduced through the tube. If the stomach is a normal one or there is some disease other than ulcer, no pain follows this procedure, but if an ulcer exists severe pain is immediately caused, which may at once be relieved by having the patient drink some milk. If no pain is caused, an endeavor is made by rubbing and by changing the position to bring the fluid into contact with all portions of the stomach wall. If there is still no pain, the author believes the possibility of ulcer may definitely be excluded. Prerequisites are an empty stomach and the presence of pain as a symptom of the malady, for the test is intended simply to accentuate what normally happens when digestion is going on. In the treatment, Bönninger has found cream an agent of great value, since it is highly nourishing, taxes the stomach but little, is fluid, causes the secretion of very little acid, and binds a great deal of acid. He is also a believer in the administration of large doses (10 g.) of bismuth with the stomach in the fasting state.

Munchener medizinische Wochenschrift, February 18, 1908.

Zinc Chloride in Carcinoma and Phenol in Endometritis.—Herff has found that the use of zinc chloride as an application in endometritis or as a vaginal irrigation, as often advised, is not satisfactory from the therapeutic standpoint and in addition is open to the objection of sometimes doing damage through cicatricial stenosis or cauterization of the vagina. The latter is especially likely to result if the solution is made up without the addition of a few drops of hydrochloric acid, as otherwise the salt does not all go into solution and the undissolved particles are deposited on the mucous membrane and injure it. For intrauterine applications in endometritis he warmly recommends alcoholic solutions of carbolic acid ranging in strength from 50 per cent. even up to 90 per cent. Iodine also is valuable for the purpose, and these remedies are superior to formalin. While chloride of zinc is not a proper agent for use in treating endometritis it forms a highly serviceable application to inoperable cancers of the uterus. The ulcerated surface is thoroughly curetted and in three or four days is well cauterized with zinc chloride. To do this a plug of cotton shaped to fit the cavity and coated with a 50 per cent. paste of the salt and starch with a few drops of glycerin is introduced and allowed to remain in position for from four to eight hours. The author has employed the method in hundreds of cases without any mishap, though instances of fatal poisoning with zinc chloride have been reported.

Carbon Dioxide Hand and Foot Baths.—Pototzky ascribes beneficial effects to hand or foot baths in which carbon dioxide is being evolved. The results are due to the local stimulation of the forming gas bubbles attended by continual slight changes in temperature which also are stimulating. The conditions in which the measure is likely to be useful include local circulatory disturbances such as habitual cold hands or feet, hyperhydrosis, and chilblains. It is also indicated in hyperemic conditions of the brain, insomnia, nervous vasomotor disorders, asthma, angina pectoris, etc. The hands or feet are immersed in the bath to the middle of the forearm or of the leg and kept there for periods of time depending on the special conditions present. The temperature of the bath is in the neighborhood of 28° C. and the gas is generated by the action of hydrochloric acid on sodium bicarbonate, or some similar method.

Boric Acid Poultice.—Mix a tablespoonful of cold water starch and a teaspoonful of boric acid with a little water; add the mixture to a pint of boiling water and stir the whole until a uniform mucilaginous mass is formed. When cold spread the jelly thickly on cotton and cover it with a piece of muslin. Then apply to the part. A good plan is to put on the poultice at bedtime and to remove it in the morning. It is useful in acute and subacute skin affections to cleanse and soothe prior to the applications of ointments, etc.—*The Hospital.*

Book Reviews.

Thinking, Feeling, Doing. An Introduction to Mental Science. By E. W. Scripture, Ph.D., M.D., Assistant Neurologist, Columbia University. Second Edition, Revised. Illustrated. New York and London: G. P. Putnam's Sons, 1907.

The new or experimental psychology, of which this book is an exponent, insists on having all statements concerning mental facts proved by experiment and measurement. This is to replace the former or old psychology, which was largely based on speculation and guesswork. The new psychology, as handled in the present volume, is interesting; it is also revolutionary, in that it tends to put psychology on the same basis as the other sciences. The subjects discussed by the author are: Watching and Testing; Time and Action; Reaction-time; Thinking-time; Rhythmic Action; Steadiness; Power and Will; Touch; Hot and Cold; Smell and Taste; Hearing; Color; Color Sensitiveness; Seeing with One Eye and with Two Eyes; Feeling, Emotions, Moods; Attention; Memory; Suggestion and Expectation; Materialism and Spiritualism. Experiments are freely introduced, some of which require special apparatus and can be performed only in the laboratory, while others are well within the powers of every reader. As an illustration of Prejudice, the author gives the following: "Seven alienists of good standing swore that according to the facts before them a certain murderer was sane; they were employed by the prosecution at $100 a day. The defense employed seven equally good alienists at $150 a day; these swore that according to the same facts the man was insane. Every one of these men was honest in his opinion—at least, as far as his consciousness went; there was at work a cause which unconsciously led him to give his opinion in a certain way; he was paid to do so." The book can be cordially recommended to the attention of all who think—and feel—and do.

Diseases of Children for Nurses, including Infant Feeding, Therapeutic Measures Employed in Childhood, Treatment for Emergencies, Prophylaxis, Hygiene, and Nursing. By Robert S. McCombs, Assistant Physician to the Dispensary and Instructor of Nurses at the Children's Hospital of Philadelphia; Assistant Physician to the Medical Dispensary of the Hospital of the University of Pennsylvania. Illustrated. Philadelphia and London: W. B. Saunders Company, 1907.

This is a concise, practical little work, giving special attention to nursing in the diseases of infancy and childhood. One point of value is that the special features of nursing in each particular disease are given in connection with a brief description of the disease. While it cannot lay claim to originality or exhaustiveness, it brings together in compact form and presents in an attractive way information that is indispensable to the nurse or the mother, who would be successful in the care of children. He has presented all the material on the subject of drugs and therapeutic measures that could be of use to the nurse, and makes no pretense of taking the place of the physician. One wishes, however, that he had given the subject of artificial feeding during early infancy somewhat fuller treatment.

Heart Disease and Thoracic Aneurysm. By F. J. Poynton, M.D., F.R.C.P., London. Assistant Physician to University College Hospital, and Physician to Out-Patients' Hospital for Sick Children, Great Ormond Street, London. Late Medical Tutor and Medical Registrar to St. Mary's Hospital. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, 1907.

The author has made the most of the space at his command in giving the essential points which have to do with the ordinary forms of heart disease; it is a very compact and accurate digest of these affections and has been put fully abreast of the times. The section on Rheumatic Heart Disease is particularly commendable in that it gives a general description from a bacteriological, pathological, and clinical standpoint which will prove of exceptional value to the student whose concept of pericarditis, for instance, is extremely vague and who looks on all the divisions of these rheumatic manifestations as separate entities. The author wisely omits the curiosities such as will rarely be met and teaches clearly and soundly what the student and practitioner encounters in his daily work. A good though short chapter on arterial disease and aneurysm occupies about twenty pages of the text, which is followed by a list of prescriptions and diets suitable for cardiac cases and a résumé of the Nauheim baths and the Schott movements. Throughout the work are twenty excellent and well selected illustrations and seventeen plates, mostly dealing with the pathology of the subject.

Röntgen Rays and Electrotherapeutics, with Chapters on Radium and Phototherapy. By Mihran Krikor Kassabian, M.D., Director of the Röntgen Ray Laboratory of Philadelphia Hospital, formerly in charge of Röntgen Ray Laboratory and Instructor in Electrotherapeutics in Medico-Chirurgical Hospital and College; Member of the Philadelphia County Medical Society, Pennsylvania State Medical Society, American Medical Association, American Röntgen Ray Society; Vice-President of the American Physico-Electrotherapeutic Association; New York Medico-Legal Society, etc., etc. Philadelphia and London: J. B. Lippincott Company, 1907.

In this work the author has attempted with some measure of success to set forth the more important facts pertaining to the Röntgen Rays and Electrotherapeutics. The author takes up his subject under three heads: (1) A general consideration of the subject of Electrotherapeutics. (2) A more or less exhaustive treatise of Röntgen Rays in diagnosis. (3) Radiotherapy, Radium and Phototherapy. Considerable space is given to the technique of skiagraphy and other applications of the *x*-ray. Dental skiagraphy has in particular received more attention than is generally accorded to this division of the subject in textbooks. The work is copiously illustrated—in fact, this feature of the book, it must be confessed, is rather overdone. Many of the illustrations fail to illuminate the text and in some instances at least it is difficult to see clearly their relation to the matter in hand except as they are perhaps excellent reproductions of photographs of the static machine and its manipulator. Such a fault, however, is of minor importance, and, in view of much that is excellent, such as descriptive matter pertaining to the use of static electricity, high-frequency currents, and the cathode rays, may be overlooked. A much more serious criticism the author deserves on other scores. First, in his failure to give due credit to the splendid work of other *x*-ray operators, both in this country and abroad. For instance, on page 312 he says: "Radiographs of the thorax have been made by von Ziemssen and Rieder in one second of time, etc.," and he fails to add that even better results than Rieder has accomplished, since the latter's work was done after Rosenthal's method, that is, with the aid of intensifying screens, have been attained in this country by Henry Hulst and others without the interposition of screens at all. Moreover the author fails to set forth clearly the real purpose of rapid exposure. He says, on page 312: "Exposure should be as rapid as possible, otherwise the incessant motions of the thoracic viscera will cause a blurred shadow." He does not state what is the much more important purpose of rapid exposure, viz., to avoid the effects of the secondary rays.

A consideration of that part of the book which deals with therapeutic application forces one to admit that the author does not always show good judgment or skilled medical knowledge. The book is lacking in such features as would make it of value to the expert, while it is rather too vague and confused to be of great use to the beginner. It may be criticised as an attempt to cover too much ground, and cannot be regarded as any improvement on already existing works on the same subject.

A Text-Book of Practical Gynecology. For Practitioners and Students. By D. Tod Gilliam, M.D., Emeritus Professor of Gynecology in Starling, Ohio, Medical College, and Sometime Professor of Gynecology, Starling Medical College; Gynecologist to St. Anthony and St. Francis Hospitals; Consulting Gynecologist to Park View Sanitarium, Columbus, Ohio; Fellow of the American Association of Obstetricians and Gynecologists; Member of the American Medical Association, of the Ninth International Medical Congress, etc. Second, revised edition. Philadelphia: F. A. Davis Company, 1907.

This book is plain and practical and for the use of the student and busy practitioner. A conspicuous innovation is the description of the technique of the operation of Goffe for extensive cystocele and that of Watkins for post-climacteric prolapse of the uterus. Full page plates serve to illustrate the latter operation. Another innovation is an index of regional symptoms of ascites, discharge, hemorrhage, pain, and painful menstruation. What pathology is given is of very elementary character and one plate is shown reversed. Among three hundred and fifty figures, about one hundred and sixty are illustrations of special instruments. Taken as a whole the book is of value and to be recommended to those who require a little more than a fragmentary knowledge of this subject.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held December 17, 1907.

DR. GLENTWORTH R. BUTLER IN THE CHAIR.

Masked Appendicitis.—Dr. ALGERNON T. BRISTOW of Brooklyn read this paper. He said that it was a common practice for the textbooks to describe a prevailing type or typical form of a disease. If a case always followed the type described in the textbooks, then mistakes would rarely be made. Diagnosis would be a matter of no difficulty. The typical cases of appendicitis were common. But the atypical cases were likewise common. The real difficulty was not in diagnosis, but in prognosis. The attitude of the family physician toward appendicitis was usually that the majority of the cases got better on the expectant treatment. It was merely necessary to review the frequent results of unrecognized or untreated cases, such as appendicular abscess, gangrenous appendicitis, diffuse peritonitis, and metastatic infection, to realize that too high a price was paid for an error in diagnosis. There were not many practitioners who would fail to advise operation in cases accompanied with violent pain, extreme tenderness, and persistent vomiting. But it was far more dangerous to wait in certain cases in which the medical attendant believed he was dealing with a mild type of the disease. Occasionally, with a temperature of 99° and a pulse of 80, the condition was nevertheless a dangerous one. In many diseases one attack conferred relative immunity for subsequent attacks. This was not so with appendicitis. In this connection the attitude of life insurance companies was significant. A case that had had one attack of appendicitis was absolutely uninsurable. Every surgeon could call to mind cases that had had several attacks, in which the last attack was fatal. Subacute attacks were frequently regarded merely as indigestion. The speaker detailed six varieties of masked appendicitis, each of which without operation would have terminated in death. Class 1 included cases in which the subjective symptoms were mild. The pulse and temperature were both low. As examples of this form, he recalled the cases of two physicians and also the son of a physician. In one of the former the patient was seen in his office fully dressed; there was pain in the right side of the abdomen, there was no marked spasm, no increased temperature nor accelerated pulse. The next day the patient was in bed; examination now showed some temperature and a slight spasm. Leucocytosis was 10,000 and the percentage of polymorphonuclears was 81. Operation revealed a gangrenous appendix. The second case was that of a house physician at St. John's Hospital. On January 14 he was well and attending to his usual duties. At 11 o'clock he had a vague pain in the abdomen. At 12 o'clock he had a slight headache and the abdominal pain disappeared. Pressure over the region of the appendix caused nausea. He took a dose of salts and at 2 P.M. went to bed. There was no rigidity of the rectus. The surgeon detected no symptoms of appendicitis. At 8 P.M. the temperature was 98.4° and the pulse 100. Leucocytosis was 18,000. The next morning pulse was 110 and temperature 99°. Operation revealed an appendix perforated at the tip, with pus free in the peritoneal cavity. The third case, that of a physician's son, was seen two weeks after the patient had returned from a camping expedition. He had complained of vague digestive disturbances. That morning he had eaten his usual breakfast. At 3 P.M. he had general abdominal pain, but this was not severe. The pulse was 90 and temperature 99°. As long as he remained quiet there was no pain. Leucocytosis was 20,000, with 90 per cent. polymorphonuclears. Operation revealed an inflamed appendix with a gangrenous tip. In the second class of cases the symptoms were not more marked than in the above, but the blood count was deceptive. An example of this variety was afforded by a lady, Mrs. P., who had been under observation for three days. When seen by the speaker she was fairly comfortable; temperature, 99°; pulse, 80; blood count showed leucocytes 14,000, with 88 per cent. polymorphonuclears. The next day the former were 12,000 and the latter was 70 per cent. In ten days the patient was removed to the hospital and then had a leucocytosis of 10,000, with 70 per cent. polymorphonuclears, a temperature of 99° and pulse 76. Operation discovered in the pelvis a highly inflamed appendix, about which there was an ounce of pus. Another case was that of Dr. A. S., who complained of tenderness over the pubic region. Leucocytosis was 20,000 and polymorphonuclear count was 70 per cent. Temperature, 99.5°; pulse, 76. Operation showed an abscess cavity in the pelvis behind the rectum. The patient had had a previous attack of appendicitis, as evidenced by the presence of old adhesions. The third type of cases were those in which the abdominal pain was referred to a region distant from the seat of inflammation. An example of this type was furnished by a patient 25 years old, who had been ill three days, and who attributed his trouble to a dose of Rochelle salts. All the pain was in the left iliac region, with tenderness in pressure. A diagnosis of acute diverticulitis was made. The patient was operated on through a median incision, which showed a gangrenous appendix deep in the right side; culture revealed a colon bacillus infection. The wound was closed without drainage. Type 4 included cases in which there was apparent recovery, with the presence of a latent abscess in the abdominal cavity. On the resumption of work by the patient, the abscess would rupture. A case of this kind was recalled as that of a dentist who had had a moderate elevation of temperature and a moderate pain in the back and on the right side of the abdomen. The pain in the back persisted, and the abdominal pain became localized in the right loin, but not in the appendiceal region. On getting out of bed the patient felt something give way. On operation there was found an abscess cavity which had ruptured and caused a general peritonitis. The fifth type of cases includes those in which there was an encysted abscess. Such a case was that of the late Dr. C. On April 21, 1885, he had had his first attack, which consisted of violent chills, high temperature and great pain. The patient died in 1892. During the interval he had had numerous attacks like the first, over a dozen of them, and had been variously treated for malaria, typhoid fever, and other things. The chills had been due to an appendiceal abscess, which had been draining into the ileum. The chills occurred whenever there was an interference with drainage. The abscess was buried in dense adhesions. There were other cases of appendicitis walking about with a large abscess in the abdomen. The sixth style of cases comprised those of chronic subacute appendicitis, the pain and tenderness were not extreme, nor were they felt in one spot. Certain articles of food disagreed. The patient had to be careful about his diet. He had occasional nausea. This type was the most frequent one of the masked forms of appendicitis. The blood count, if it could be of any value, had to be made by an expert. There was usually revealed a leucocytosis and a high percentage of polymorphonuclears. One attack conferred no immunity against subsequent attacks. Two attacks were serious. These were the cases that furnished most of the mortality from appendicitis. No one could tell anything about the real condition of the appendix except from inspection. Over 75 per cent. of the cases of appendicitis that went to operation were pus or gangrene cases. The speaker was personally in favor of operation twelve hours after the beginning of an attack.

Dr. H. BEECKMAN DELATOUR of Brooklyn said that the

speaker had so fully set forth this subject that he could only emphasize what he had said by iteration. So many cases gave a history of previous attacks that when a patient was said to be cured after a first attack he was really not cured. It was most unfortunate that one had to go over the ground again and again. To be sure, there were some cases in which it was advisable and rational to delay, and to advise against operation. Such were cases of a mild type, in which the patient was neurotic or had a bad heart, and also cases of obese individuals, with low temperature and moderate tenderness, who improved within twenty-four hours. Dr. Bristow's classification was very good. The speaker cited the case of a young woman in whom the pain was referred to the umbilicus. Incision was made in the median line, but it was difficult to satisfy the operator that he had a case of appendicitis to deal with. Fairly common were these cases of apparent recovery with abscess. He cited the case of a young boy who had recovered from an attack of typhoid fever, and was out playing ball; suddenly he felt a severe pain and died six hours later from a ruptured abscess. There were cases of chronic low-grade appendicitis with vague symptoms of intestinal indigestion.

Dr. Walter C. Woods of Brooklyn cited a case of inflamed femoral hernia with a gangrenous appendix in the sac. There were also cases of appendicitis associated with typhoid fever. There were also cases in which the symptoms were those of typhoidal infection of the appendix. These cases got well with or without operation. Rarely did they run on to suppuration. It was sometimes necessary to differentiate between perforation of an intestinal ulcer and perforation of an appendix. In children during the summer cases of underlying appendicitis were frequently overlooked, being masked by a gastroenteritis or enterocolitis. Twenty years ago Gibney had spoken of cases of abscess of the appendix being mistaken for hip-joint disease.

Dr. Frederick S. Dennis of New York said that vomiting, rigidity and a rising leucocytosis were the cardinal signs that an operation was necessary. Even a falling leucocytosis with persistence of the other symptoms did not make less urgent the need of an operation.

Certain Evil Tendencies in Medicine and Surgery.—Dr. Maurice H. Richardson of Boston, Mass., read this paper. He said that he greatly enjoyed the paper that had just been read, and admired the manner in which these obscure cases had been studied. This was such a practical paper that it was with great diffidence that he read his own, which was not so practical. The title was misleading. The adjective evil was too strong. It would take a long time to frame a satisfactory definition of the word evil. In examining the early volumes of the *Boston Medical and Surgical Journal*, he was struck by the reports of cases that exhibited the widespread tendency as at present to be satisfied with hasty diagnosis. An example of such hasty diagnosis was afforded by the case of a man past middle life, who was sent into the hospital with the diagnosis of enlarged prostate. Complete anesthetization enabled the speaker to make a diagnosis of inoperable cancer. In 1828 every surgeon, as to-day, occasionally made a mistaken diagnosis as to the presence of stone in the kidney. The speaker said that he took the field against the diagnosis of renal stone without the evidence afforded by the *x*-ray. In the early days, the *Lancet* and other medical journals frequently indulged in sarcastic criticism of operative failures and did not hesitate to lash the unsuccessful operator. To-day, it remained for the surgeon to show up his own mistakes. The surgeon had to walk in the straight and narrow path. In many hospitals there were rules which prevented an operation without the consent of the rest of the staff. Mistakes in diagnosis were often the result of inadequate study. He believed that as a rule conclusions were right, but that facts were wrong. Each symptom had to be given its weight. It was thorough and adequate study that enabled Fitz to perfect the diagnosis of acute pancreatitis. It was the rule, rather than the exception, to make this diagnosis. Diagnoses were often made upon too hasty observation of inadequate data. The patients were frequently dissatisfied at the failure of the physician to make a hasty diagnosis. But adequate investigation was necessary for a careful diagnosis. In the first place it was necessary to get a careful history and to make a painstaking physical examination. It was necessary to cross-examine the patient and read the history to him. Another tendency of modern surgical practice was that toward the operative diagnosis. The question that seemed to present itself was, why should the physician spend his time in trying to make a diagnosis when an exploratory incision would settle the diagnosis at once? But many a life was lost on account of this effort toward the operative diagnosis. The resort to the operative diagnosis discouraged the other method of painstaking examination and deduction. The exploratory operation was to be the court of final decision in doubtful cases. There were cases of mistaken operative diagnoses. A case was recalled in which a cicatricial pylorus was removed for cancer. The speaker emphasized the importance of an accurate history to look back upon to aid the exploratory diagnosis. In diagnosing conditions about the gall-bladder it was worth while to remember that jaundice might have been due to thickening of the head of the pancreas. There was a tendency among surgeons to make light of the surgical operation. It was necessary to weigh the contraindications more than the indications. In abdominal surgery the evils of an unguarded prognosis were chiefly seen. It was necessary to abandon entirely the faith in a short cut to diagnosis and to go back to the old-fashioned history and careful examination. The surgeon had to combine a calm and judicial temper that carefully weighed all the evidence with the highest mechanical skill.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 7, 1908.

Dr. Charles H. Peck in the Chair.

Seminal Vesiculotomy to Date.—Dr. Eugene Fuller said that he had performed this operation 101 times and without a fatality. Out of this number the operation had been undertaken twenty-three times for the relief of gonorrheal rheumatism. His first four cases of seminal vesiculotomy for gonorrheal rheumatism were reported in the Annals of Surgery, June, 1905. In all of the twenty-three cases the operation had had a profoundly beneficial effect on the rheumatism, all the patients having left the hospital in a well or a greatly improved condition. In all these cases there was, of course, a seminal vesiculitis to account for the focus from which the systemic absorption originated. Out of the twenty-three cases seventeen were cured as a direct result of the operation and were well when last seen. Of the remaining six two got well after the operation and remained so until about one year, when each of them contracted gonorrhea afresh. Rheumatic symptoms then reappeared. Both of these patients were then seen but once with moderate rheumatism, after which trace of them was lost. Two more, after leaving the hospital in a very satisfactory condition, immediately resorted to sexual intercourse. The sexual exercise during the convalescent stage from the operation naturally reinflamed the seminal vesicles, and there was a relapse of the rheumatism. In both these cases, however, the rheumatism again disappeared after the effect

of the premature sexual exercise passed off, and these patients were now well. Two very chronic cases relapsed, one after being well eight months after operation, and one after being relieved three months. In both these cases there was a recrudescence of the tenderness and inflammation in the seminal vesicles. They were destitute individuals and probably exposure and poor living were to blame for the relapse. In the acute bedridden patients the effect of the operation was most marked. In twenty-four to thirty-six hours the pain in the joints disappeared and by the fourth day the swelling. Some stiffness and some atrophy of the muscles were of course left after the rheumatic process had disappeared in these acute cases, requiring massage and passive movements. In the chronic cases the pain disappeared in a week or ten days, and at the end of two weeks massage could be prescribed. In the very chronic cases it might take from two to three months of massage and exercise to limber up the joints which had been robbed of their function. In fact, one had the same problem in these cases which the surgeon had after resolution from a fracture of standing. It was well known that in chronic gonorrheal rheumatism massage and manipulation made matters worse; whereas in these cases of convalescence after the seminal vesiculotomy such treatment was beneficial because there was no longer the systemic absorption of the toxin. In many of the chronic cases the preceding gonorrhea was so remote an affair that the existing rheumatism had supposedly had no connection with it. In these cases the diagnosis of uric acid, chronic rheumatism allied to the so-called inflammatory form, arthritis deformans, gout, neuritis, and neuralgia, had been made to account for existing conditions. The physician or orthopedic surgeon rather than the genitourinary surgeon had been consulted for most of these cases. He exhibited the following illustrative cases:

The first patient he presented was a man, 30 years old, operated on by him in early January in the City Hospital. He had a chronic gonorrheal rheumatism of eight years' standing. Both knees, hips, spine, and neck were involved. The back was bent, and there was no mobility to the spine and but very little motion to the neck. He had been on crutches for a year before the operation. He acquired his first gonorrhea nine years ago and a second attack four years ago. Both seminal vesicles were thickened and embedded in a preseminal vesicular sclerosis. Vesical vesiculotomy was performed five weeks ago. The thickened sclerosed tissue surrounding the seminal vesicles was cut through on each side and the seminal vesicles were freed from the surrounding adhesions, after which both sacs were freely incised, packed with gauze, and drainage tubes were adjusted. In this case, owing to the chronicity of the lesion, there was no active intraseminal vesicular catarrh, the sac walls being in fact compressed and somewhat atrophied. A few intracellular diplococci were found in a smear taken from the region of the sac cavity. One week after the operation the patient could move his back and neck quite freely without pain. He was now walking about without crutches or cane. The affected joints were still somewhat stiff and the muscles had not yet recovered wholly from their atony, but these symptoms were rapidly disappearing as the result of massage and exercise.

The second patient that he presented was a man, 45 years old who was operated on about seven weeks ago at the City Hospital. He entered the hospital owing to trouble in connection with his left knee, which he had had apparently for four months. The knee was the seat of a hard inflammatory tumefaction, consisting apparently of an exudation. This exudation had caused complete ankylosis. The joint was tender on deep pressure and much pain and tenderness resulted when the weight of the body was put on the joint. The patient gave a past history of severe gonorrhea or relapsing urethral discharge. His sexual function was also impaired. At the time he entered the hospital he felt that he had no gonorrhea or urinary inflammation. Medical and the orthopedic form of treatment had been tried with no beneficial effect, and the patient was then transferred to Dr. Fuller's service. The examination showed that he had a chronic seminal vesiculitis, especially in connection with the right sac, the lower portion of which was enveloped in a sclerous exudate. Seminal vesiculotomy was done, the sclerous exudate cut through, and the sac freed from the adhesions and freely incised. The painful sensations quickly left the joint after the operation and were followed more slowly and gradually by a resolution of the hard exudate. With the disappearance of the exudate the joint motion had gradually returned. Now the patient walked about without pain and with much movement in the joint; this movement was increasing rapidly.

Dr. Martin W. Ware said that Dr. Fuller did not state that these cases were cured, but somewhat relieved. He asked how one could expect these gonorrheal cases of rheumatism, which appeared to be hopelessly ankylosed, to come around and limber up. If there was an infection from the seminal vesicles he asked how they were to exclude the possible fact of the prostate being involved as well. He also asked what were the real indications for advising patients to undergo such a formidable operation.

Dr. Eugene Fuller replied that patients with gonorrheal rheumatism would not stand massage, but after vesiculotomy massage improved their condition very much. The operation was devoid of danger when properly done and in trained hands. He cautioned against cutting into tuberculous vesicles. It was very hard to get smears in these cases. The genitourinary symptoms disappeared, as a rule, and so they consulted other specialists, went to spas, etc.

Infected Compound Fracture of the Tibia Treated with Intracanalicular Aluminum Splint.—Dr. W. H. Luckett presented this case. This patient sustained a fracture of both tibia and fibula, and of the thigh at the junction of the middle and lower thirds, all on the same side, as well as other injuries. One month later the ends of the tibia were found to be necrotic, and much pus was evacuated; pus was gotten with a six-inch scoop. He wanted to amputate the limb, but the patient refused. The temperature was 102°. The intracanalicular aluminum splint was applied, such as devised by Dr. Elsberg, and the patient went on to a good recovery. This splint extended up so as to include the fractured thigh. The wound healed with an adherent scar, in the center of which was a small sinus which was still discharging pus. It was his opinion that the aluminum tubes will have to be removed. He presented this case to show what ultra-conservative surgery was capable of accomplishing.

Dr. John J. Moorhead, who also had seen the patient at the time of injury, considered the case particularly bad because of the complicating fracture of the thigh on the same side. The outcome was very satisfactory.

Dr. Martin W. Ware presented an aluminum splint that had been removed from a patient; it had been in place three or four weeks and had been inserted because of non-union. The interior of the splint contained organized tissue and some marrow cells and granulation tissue. After four weeks the wound healed, and yet there was a sinus that discharged pus. There was a great deal of plastic material about the periosteum.

Dr. Joseph Wiener presented an aluminum splint. He saw a patient after a heavy beam had fallen on his leg, resulting in a compound fracture of both bones. His temperature was from 102° to 104°, and he had lost forty pounds in weight. His pulse was from 110 to 120. The patient looked as though he was doomed. Amputation was advised against. The suppuration was very marked and

ran above the knee. He lost almost the entire skin of the leg from the ankle to the knee on the inner aspect. Pus burrowed between the muscles. A large amount of the tibia was necrotic, and it was impossible to remove all the diseased bone. Enough of the diseased ends of the bone was removed to enable him to bring them together and fasten with silver wire. The intracanalicular aluminum splint was introduced. This was about as desperate a case as one had to deal with. Abscesses developed and extended up to Scarpa's triangle; abscesses developed between the muscles; there was an enormous denuded area, in the center of which a bone sinus discharged pus. Grafting was impossible because of that. The leg was swung in a cradle, and the bone sinus packed with iodoform gauze, which was frequently changed. Small grafts were applied and they all took. The bone sinus persisted. Six months after the original operation he found the internal and external surface of the tibia had been replaced with a firm callus, and the splint was presenting in the wound. He chiseled through the aluminum splint, and so was able to get the pieces out. The medullary canal was cleaned out and filled with a spermaceti mixture. It required three weeks for the wound to heal. To-day the patient was absolutely well, and the limb supported a weight of 200 pounds. He was able to stand on the affected leg without support.

Dr. Charles A. Elsberg said that he was very much gratified at the way the splint had been taken up by his colleagues. His method had not yet been published, as he was waiting for more cases, and wished a wider and larger experience before writing of the advantages and disadvantages of the aluminum splint. The splint was of value in infected cases, because it formed an aluminum hydrate in the body, and this was an antiseptic. Therefore, the splint was capable of sterilizing itself.

Dr. W. H. Luckett closed the discussion.

Disappearance of a Recurrent Round-Celled Sarcoma with Metastases After Two and a Half Months' Treatment with the Mixed Toxins.—Dr. Wm. B. Coley presented a patient, 27 years old, always in good health, with family history good, and with no history of injury. The patient first noticed a tumor in the lower lumbar region in September, 1907; it grew with great rapidity and was operated upon in the latter part of September by Dr. J. C. Biddle, of Fountain Springs, Pa. The tumor then was the size of the two fists. The pathological examination of the growth was made by Dr. John Funke of the Jefferson Medical College Hospital, who pronounced it to be a large round-celled sarcoma. On November 19, 1907, the patient was admitted to the General Memorial Hospital. Examination showed an unhealed wound in the lumbar and gluteal region, 6x8 inches in area, the unhealed portion being the shape of an excavation about one inch lower than the surface of the surrounding tissue. The lower jaw showed a tumor beginning about one inch to the left of the symphysis, extending to the left nearly to the angle of the jaw, the growth seemingly occupying the entire thickness of the jaw. The patient was at once put upon the mixed toxins, ¼ mg. being the initial dose given in the gluteal region. This was gradually increased until a temperature of 102°-103° was obtained. Under these systemic injections the tumor of the jaw slowly became smaller and much softer. As it became fluctuating, he made an incision over the protuberant part and found a highly vascular tumor extending down to the periosteum. The patient's general condition slowly began to improve under the treatment. At the present time the patient had gained sixteen pounds in weight, and there was no longer any evidence of a tumor either in the jaw or the lumbar region. The wound had entirely healed. He had had altogether forty-nine injections of the toxins, beginning with ¼ mg. and increasing to 8 mg. All but five injections were systemic into the buttocks.

Large Incarcerated Femoral Hernia, Containing Intestine and Suppurating Fallopian Tube.—Dr. Wm. B. Coley presented a woman who had had a hernia for several years. In view of the fact that she had had several attacks of almost complete obstruction, it was thought wise to perform an operation. On opening the sac, to which the entire contents were firmly adherent, the sigmoid flexure, descending and part of the transverse colon, and a large loop of small intestine were found, all glued together with firm adhesions. After separating these adhesions, a hard mass was found near the neck of the sac, which proved to be the Fallopian tube: the tube was found to be necrotic near the neck of the sac; an abscess was opened which connected with the pelvis. From this nearly a pint of pus was evacuated. After working nearly an hour he was able to reduce the hernial contents into the left iliac fossa. No attempt was made to close the femoral ring, which was packed with gauze, and the abscess cavities were drained by two rubber tubes. Although little hope was entertained that the patient would stand the shock of the operation, she made an uninterrupted recovery, and, aside from a slight bulging in the femoral canal, was now in good health.

Dr. Herman A. Haubold said that he had had a case of three months' standing of sarcoma of the extensor vagina femoris, which was as large as a cantaloupe; it was excised freely and widely, but without avail. At once he began the use of Coley's toxins; the patient was treated persistently with the mixed toxins, and at the end of eight months the sarcoma recurred at the original site of the lesion.

Dr. Charles Goodman reported a case of polyp of the rectum, a section of which was referred to the pathologist, who reported it to be undoubtedly sarcoma. Radical operation was recommended, but refused. He left the hospital. One year later he returned and stated that he had had some operation performed and the entire mass had been removed. He now had a large mass filling the sigmoid and rectum and he was losing large quantities of blood. A laparotomy was performed and he found the pelvic and the retroperitoneal glands involved, and so closed the wound. The patient was then referred to Dr. Coley. He was admitted to the General Memorial Hospital and received the mixed toxins. Some weeks later the mass showed a certain amount of shrinkage. The injections caused him so much pain that he refused to submit to further treatment. In another case the mixed toxins were used as a prophylactic measure. The sarcoma involved the upper part of the humerus and the shoulder joint. The man was 18 years old. He had thirty injections of 3 mg. each. This patient improved very much and gained fifteen pounds in weight and felt much better than he had in many months. It was hard to say just how much Coley's fluid had done for this patient, but Dr. Goodman said he was inclined to credit the toxins with a certain amount of benefit.

Dr. John Rogers said there was a place where criticism became a therapeutic nihilism. Because one man could not cure a case, did not mean that the treatment should be discarded. Any man afflicted with sarcoma would stick to the mixed toxins until the last gasp. He said it was very foolish to say Coley's mixed toxins were of no value.

Dr. Wm. B. Coley said that the cases treated with his mixed toxins were only those that were regarded as hopeless cases; the fact that so many cases had been saved seemed to him to make it worth while to use the method rather than to give it up.

Intestinal Obstruction Caused by Trauma.—Dr. A. V. Moschcowitz said that the child he presented had been referred to him September 3, 1907. About eight weeks prior to this, while playing upon the street, she was run over by a wagon; so far as could be learned, it passed over her abdomen. She was immediately taken to the

hospital; operation was advised, but refused. The mother then took her home. On the day following the family physician was called in. The child appeared well for two weeks, when she began to vomit, and complained of occasional and cramp-like pains in the abdomen, and became constipated. Because she could take no nourishment she became emaciated. This lasted six weeks when Dr. Moschcowitz saw her. The abdomen was so thin that violent and active peristalsis could be readily seen. She was taken to the Mt. Sinai Hospital and operated on. There was an intestinal obstruction. There was found an extremely dilated small intestine, the walls of which were very thin, and there was a mass of thickening between this enlarged small intestine and the intestine leading from it, causing a constriction which produced the obstruction. This necessitated a side-to-side anastomosis with a Murphy's button. This button did not pass and could be felt in the right iliac fossa. Otherwise the child was perfectly well and was discharged from the hospital. On September 3 she was operated on and was kept under weekly observations until November 2. Two weeks after her discharge she complained of pain from time to time and violent cramp-like pains in the abdomen. The button was felt in the cul-de-sac of Douglas. It was the retention of the button that caused these symptoms, and the mother consented to operation. The child was readmitted January 5 and operated on next day. This button was found to be perfectly loose in the dilated portion of the small intestine. The bowel had become shrunken. Over the intestine which had been anastomosed there was a triangular space about three inches long, with absolutely no mesentery, not even a trace. The Murphy button was removed through an incision made in the intestine, and then the omentum was sutured in such a way as to wrap it up; this would make it viable for a long time.

Dr. John Rogers asked what Dr. Moschcowitz's interpretation of the injury was.

Dr. Moschcowitz said that the wagon wheels passing over the abdomen crushed the coats of the intestine, so that their tone was lost, and made the intestine less resistant to pressure from the fecal contents; this permitted the dilatation to take place.

Case of Tuberculous Lymph Nodes.—Dr. Charles N. Dowd presented a case of lymph node tuberculosis where large masses of these nodes had been removed through a transverse incision.

Technique of Early Operation for Tuberculous Cervical Lymph Nodes.—Dr. Charles N. Dowd read this paper. He said that the effort to produce thoroughness in this operation had frequently led to an utter disregard of the scars which were produced; in certain advanced cases this disregard was to be advocated; in other instances, however, a scar-saving operation was compatible with thoroughness. The infection in about 85 per cent. of the cases, as they appeared in New York, first involved the subparotid group of lymph nodes, the nodes that formed the first barrier to the spread of the infection from the pharynx and tonsillar region; it was usually confined to this group or its vicinity for several months. He showed plates giving the details for a radical operation for the removal of the infected nodes during this period through a transverse incision, which was made about an inch below the angle of the jaw, and which was placed either in or parallel to a neck crease, and which was followed by a very slight scar. The plates indicated an exploration of the node containing area from the mastoid nearly to the clavicle. He reported on sixty-seven of these early cases. All recovered from the operation within a reasonably short time. There was only one disturbing complication. A secondary hemorrhage from the internal jugular vein on the ninth day. This was followed by recovery after ligature of the vein. All but fifteen of these cases had been followed for periods from a few months to four years. There were only four recurrences. The appearance of these cases as they had been examined at various periods after operation had been almost uniform. They usually presented a few quiescent pea-sized nodes in the posterior chains, which were hyperplastic, not tuberculous. Among these sixty-seven patients there were three who had filbert-sized nodes, which might be regarded as recurrences. In the fourth one a discharging sinus appeared in the wound area; this closed spontaneously. He also had a node removed from the parotid gland by operation. There, no doubt, would be some other recurrences among these sixty-seven cases, but the present report of only four recurrences was surely very encouraging. There were of all Dr. Dowd's cases, extensive and otherwise, 256, and there was but one death, following operation, in the entire number, from secondary hemorrhage from the internal jugular vein, ten days after operation. These cases had been followed for long periods, varying from twelve years down. They bore out the indication of the report made in 1905 of between 75 and 80 per cent. apparent cures, and in many other cases the patients would probaby be found to be cured after further observation.

Dr. H. A. Haubold discussed this paper.

Primary Cancer of the Appendix.—Dr. Clarence A. McWilliams read this paper. The rarity of this condition rendered the report of the following case interesting. An immigrant girl, 20 years old, was brought directly to the Presbyterian Hospital from the steamer, September 5, 1907. Save for seasickness, she had been well up to two days prior to landing. Then she was taken with severe pain in the right side of the abdomen. She had never been ill before in her life. She had fever and was markedly prostrated. The right lower quadrant of the abdomen became very tender to the touch. Her temperature was 101° and pulse 100. The leucocyte count was 23,000 and the polymorphonuclears 88 per cent. She was well nourished and showed no signs of cachexia. Heart and lungs were normal. The abdomen was distended and there were no respiratory abdominal movements. The whole right lower quadrant was rigid and very tender and at McBurney's point was felt a mass the size of a lemon. Over this mass there was tympany, but there were no signs of free fluid in the abdomen. At operation the inserted finger pushed aside an adherent coil of intestine, which opened an abscess, well walled in, containing about two ounces of fetid, thick, creamy pus. After sponging this dry, the appendix was found hanging over the brim of the pelvis, to whose walls it was adherent. It was four inches long and as large as the finger. The serosa was congested, and about one inch from the base was a gangrenous patch, in the center of which was a small perforation. The appendix was amputated. The girl left the hospital on the thirteenth day. At the time of the operation there was no suspicion that the appendix was cancerous. The pathological report was that it was a carcinoma of the appendix, polyhedral cell type. Also an acute appendicitis. In 1906 Rolleston published a paper containing all the cases which had been reported up to 1906, 42 in all, all doubtful cases having been thrown out. Dr. McWilliams said he had found 49 cases in addition to the 42 of Rolleston, making a total of 91 undoubted cases in all. Of the 91 cases, 23, or 36.5 per cent., were operated upon during or immediately after the first acute attack of appendicitis, while 40, or 63 per cent., had had symptoms of chronic appendicitis in some form for varying periods of time. In over 50 per cent. of the chronic cases the symptoms had lasted for a year or more. In eight cases the appendices, which were found later to be cancerous, were removed in operations performed for other pathological lesions in the female pelvic organs. In two cases cancerous appendices were found to be responsible for persistent iliac sinuses. Ten primary cancerous appendices were found at autopsy. In none of Dr.

McWilliams' 49 cases was a diagnosis of cancer of the appendix made before operation. The average age of all the patients was 29 years; 63 per cent. of all the cases occurred before the age of 30. With regard to sex, 58 per cent. occurred in women and 42 per cent. in men. Enlarged lymphatic glands were present in only six out of the 91 cases. In only five cases of the 91 were concretions found in the appendix. The tumor was situated at the tip of the appendix in 42 cases, or 57 per cent.; in the middle in 10 cases, or 13 per cent.; near the base in 11 cases, or 15 per cent. In 73 per cent. of the cases the cancers were situated at or distant to the middle. Naked eye appearances of the cancerous appendices were given in the records of 44 of his own 49 cases. The tumor was visible to the naked eye in 17 cases, or 38.6 per cent. of the whole. General columnar celled cancers were found in 18 cases out of 74, or 24 per cent., and the spheroidal celled type in 38 cases, or 51 per cent. The colloid cancer occurred only in three cases. In conclusion Dr. McWilliams said that these small cancers of the appendix were not *per se* to be diagnosticated. The symptoms were those of a simple appendicitis, usually of the chronic recurrent type. Its age incidence corresponded to that of ordinary simple appendicitis. It probably occurred in about one-half of 1 per cent. of all cases of appendicitis, and this fact would more surely cause them to advise appendectomy. For the seemingly good prognosis of appendix cancer was more apparent than real, for histologically it had an outspokenly malignant character, with a tendency to involve the mesoappendix and the cecum. Whether the cancer was the primary lesion and the appendicitis the secondary, or *vice versa,* from the patient's standpoint, made absolutely no difference. The main thing for him was to be rid of his cancerous appendix as early as possible. Such an appendix cancer would almost always be discovered only by an operation. Benign tumors of the appendix were very rare; hence any circumscribed appendix tumor always should make one suspicious of cancer. He thought, perhaps, it would be better to remove the entire mesoappendix habitually in all operations for appendicitis, as this did not increase the risk of the operation. This would seem advisable, since these tumors had a tendency to involve the mesoappendix even when they were very small. Every removed appendix should be carefully examined microscopically.

Dr. Charles N. Dowd called attention to the necessity of looking for this condition continually, and that the rule should be made of having all these appendices examined.

Dr. H. A. Haubold said that the admonition should be given to all to have these appendices examined in all cases.

A New Surgical Electric Motor.—Dr. W. Sohier Bryant presented this electric novelty, which was used for bone surgery. It could be held in one hand and would drive a fraise with great rapidity and efficiency, and was sterilizable. It was an induction motor, 3-10 horsepower, 3-phase, 10 volts, 1,500 revolutions per minute, 185 cycles, 2 poles; weight, 7 pounds. The fraise used had but one cutting edge.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 13, 1908.

Dr. Eli Long, Chairman Pro Tem.

A Case of Mongolian Idiocy.—Dr. Matthias Nicoll, Jr., exhibited a patient, nineteen months old, who presented a peculiar symptom complex, rendering the diagnosis somewhat uncertain. Both parents were in good health, and gave no history that would have any bearing on the case. The baby's weight at birth was six pounds, and the mother at once noticed the eyes to be somewhat prominent. The child was fed on the breast and was well nourished up to the sixth month, when she had an attack of cervical adenitis and erysipelas, keeping the baby ill for three months. Severe gastrointestinal disturbances accounted for a marked loss of flesh and loss of weight. When one year old the liver and spleen were found to be enlarged. Five weeks ago, when the baby was brought to the clinic, the tongue protruded and there were other signs of cretinism; but upon a more thorough examination this diagnosis was abandoned. There was a double glaucoma. The spleen was felt below the umbilicus, and the liver was below the free border of the ribs. The temperature varied from 96° to 103°, and the child weighed sixteen pounds. The anterior fontanelle was still open and she had eight good teeth. The hemoglobin was 63 per cent., the red cells 3,820,000, leucocytes 11,500. In the stains were found marked poikilocytosis, polychromatophilia, no nucleated reds. Dr. Ewing, who made the blood examination, thought the case tended to the type of pernicious anemia. It was, in his opinion, best to call it severe secondary (pernicious) anemia, and the cause would probably be found in the history of the severe gastrointestinal disturbances. So far as the mental symptoms were concerned they showed the characteristic mental deficiency. He believed the case to be one of Mongolian idiocy.

Dr. Henry Berg said that ten years ago he saw a case in which the liver was as large as in the patient presented; it was hard, had a very sharp border, and there was an enlarged spleen. There was an exophthalmos. He first noticed a blowing murmur, somewhat musical in character, over the apex; one year later, in the same situation, a loud blowing murmur was found. He diagnosed the exophthalmos as being due to the cardiac insufficiency, complicating a mitral lesion. The enlarged liver and spleen were probably congenital. This exophthalmos was accounted for as being one of the signs of congenital cardiac lesion.

The Indication for Stimulants in Pediatric Practice.—Dr. Sara Welt-Kakels read this paper. The promise of recovery from disease depended upon the relative integrity of the heart muscle and the prevention of cardiac impairment which threatened the child even more than the adult. This would be accomplished not so much by the giving of cardiac stimulants as by avoiding the depressing drugs, or those which might derange the stomach, producing flatulency which so seriously interfered with cardiac action. The aimless administration of cardiac stimulants was often productive of much harm. Alcohol she considered to be the best, or one of the best, cardiac stimulants; it had a nutritive value as well. In acute fevers, when the little patient became depressed and the pulse was compressible and soft, between 120 and 130, the so-called precritical stage, alcohol was required. In cases of sepsis alcohol might be used in large amounts without unpleasant effects. In cases of erysipelas with profound sepsis in the infant, generous doses of alcohol and camphor were required. In the profound sepsis in children ill with diphtheria it was almost impossible to give too much alcohol. Kerley had mentioned a child of fourteen months, ill with diphtheria, taking four ounces of brandy in twenty-four hours. At the onset of cardiac weakness in acute fevers, digitalis, strophanthus or strychnine was indicated. The cumulative effect of digitalis was more prone to occur in children than in adults. This drug should not be used indiscriminately. When signs of failing compensation occurred, this drug should be given in comparatively large doses until its effect was noticed. In children with congenital cardiac lesions, such as communicating ventricles, digitalis might prove dangerous. To restore the circulation in certain cases, when pharmacotherapy failed, venesection and hypodermoclysis might be resorted to. Venesection was again gaining in favor, but more especially in the older children. Opening the vein in the very young child was

a very difficult procedure. Hypodermoclysis rendered the toxins circulating in the blood less effective and it supplied water that was needed to the system. It also raised arterial tension, stimulated the action of the kidneys and was excellent as a life saving measure.

The Use of Analgesics in Pediatric Practice.—Dr. Le Grand Kerr of Brooklyn read this paper. He summarized as follows: (1) They were all more or less transient in their effect, except in the case of a very few of the weakest ones. (2) They were all more or less objectionable, (*a*) because of the liability to the formation of the drug habit; (*b*) because of the irreparable damage done to a developing nervous system when their use was prolonged; (*c*) because of the dangers of overdosage (by accumulation); (*d*) because of the irritant effect which most of them possessed.

There were some well-defined rules in their administration, as follows: (1) They must be given only when absolutely necessary and after a careful consideration of the relief which might be obtained by their external and local rather than their internal administration. (2) They should not be given at a time or in such a manner as to obscure the diagnosis. (3) The cause of the pain must be removed whenever possible before the internal administration of an analgesic. (4) The dose should be very small at first and for three reasons: (*a*) The child might be susceptible to the drug used. (*b*) Relief might be obtained by the first dose and relief from pain in a child once established tended to continue. (4) The opportunity was offered for an increase in the dose later on if the demand arose. (5) Any one agent must not be used for a long time, but a change must be made from time to time to avoid tolerance and habit. (6) The dose should be small and frequently repeated instead of an initial large dose.

The Place of Hydrotherapy in Pediatric Practice.—Dr. Frederick K. W. Grosse presented this paper. After quoting the conclusions of Hecht who in 1907 reported his results of bathing children ill with measles in half baths of 68° twelve minutes without friction, and reported the temperature readings, he said that Hecht had concluded that the physical regulation of the heat in the child was indifferent. Rubner had shown that the surface of the child was in inverse proportion to its weight; therefore, the relative larger surface made the bath more pronounced. He believed it was wrong to apply low degrees in childhood, and Hecht's 68° was extreme. The child's bath should be 10° or 15° warmer than in a corresponding condition in the adult. The duration of its application should be as short as possible, without spoiling the result. With regard to the question of hardening, Kneipp recommended submersion in water of 60° for a few seconds up to one minute; but Hecker showed that nervousness, restless sleep, anemia, catarrhs, etc., could be found in children who were presumed to be hardened. In disease the practitioner might avail himself of either the rub, the bath, the wet pack, or cold compresses. According to the age a sponge was used, a linen mitten, or a rougher material, to give the rub or friction. There were no contraindications to rub in measles or scarlet fever; in the severer diseases, as infantile palsy, typhus, epidemic meningitis, acute rheumatism, etc., the treatment was given between other applications. The half bath was used, and was permitted with friction. The more virulent the infection, the more vigorous the friction. The younger the child the shorter the bath. The hot full bath of 107° was of value in collapse, to promote the appearance of rashes, and in cerebrospinal meningitis. The wet pack was of value in cases of measles, scarlet fever, bronchitis, and bronchopneumonia. In acute rhinitis and all forms of cough, the Bälz bath was a sovereign remedy. This bath was also efficacious in nephritis. Cramps of any origin, and many other conditions, offered a thankful field for this hydrotherapy.

The Principles of the Climatic Treatment of Children.—Dr. F. L. Wachenheim read this paper, and considered the temperature, the various phases of atmospheric moisture, and the pressure of the air, the last being chiefly modified by elevation above the sea level. In applying physical therapeutics of all kinds, including climate, there were training or developing the diseased body by exercise, and aiding the restorative powers of nature through reduced functional activity, or a rest cure. The former was indicated when there was impaired function of development: the latter when the body was overstrained and unable to cope with the work that normally fell to it. The climatic rest cures were especially indicated in such affections as nephritis and uncompensated cardiac lesions. Temperatures above the indifferent point were not at all restful. Young children bore cold climates poorly. Rain was useful in moderation, as was a winter sheet of snow, laying the dust, but alterations of frost and snow were objectionable. The relative low humidity was extremely valuable in lowering the sensible temperature or raising the indifferent temperature for such cases as called for a free transpiration; here a warm and moist climate was indicated as being the best diaphoretic known. High altitudes were admirable as a general tonic in torpid states, but was contraindicated in severe organic diseases, when rest was the indication. The anemias of young children did best at moderate elevations, and the same was true in victims of general malnutrition, rickets, scrofulosis, and chronic tuberculosis.

Dr. Herman F. L. Ziegel said that he had spent nearly one year in Southern California, and had been impressed with the fact that measles, diphtheria, and scarlet fever were seldom of septic types, and seldom were followed by complications. Measles was not more thought of there than was chickenpox here. They had what was called "all the year round" climate. It meant that the temperature in winter was about ten degrees lower than the summer temperature. Bronchopneumonia was a very mild disease and, as a rule, without complications. Recurrent attacks of tonsilitis in children with rheumatic pains were rarely seen in children in Southern California. In closing he said he would like to know what altitude caused anemia in some cases, while it cured in others.

Dr. F. L. Wachenheim said that people living in Denver had 7,000,000 erythrocytes; therefore, if persons went from a lower altitude with but 5,000,000 red cells, they would suffer from anemia, and this anemia resembled the anemias following severe hemorrhages. People going to Denver suffered at first a relative anemia because when they should have 7,000,000 for this altitude, they only had 5,000,000. However, after a week's stay there, one no longer suffered from anemia. There were certain anemias—chlorosis, for instance, that were benefited at Denver's altitude—but this was not true of the secondary anemias in children.

Dr. Henry W. Berg said that venesection in children was very dangerous and for several reasons. It was a difficult matter to find the veins in these young children. Children stood the loss of blood badly. The so-called coal-tar preparations he believed to be particularly contraindicated in children.

Dr. Henry Dwight Chapin said that antipyrin was one of the most efficacious drugs they had in the treatment of whooping-cough, but it should be given with care.

Dr. B. Van D. Hedges of Plainfield, N. J., recalled a very desperate case of diphtheria in which he ordered thirty drops of brandy to be given every two hours; but the nurse, anticipating the custom of Dr. O'Dwyer, in whose service the case occurred, administered tablespoonful doses instead and with marked improvement. These were the days before the serum treatment of diphtheria.

Dr. Frederick K. W. Grosse said he had used no stimulant except alcohol in his practice, extending over fifteen years. The increase in the number of erythrocytes from

5,000,000 to 7,000,000 in a short time was not so easy of explanation as Dr. Wachenheim had inferred. Hydrotherapy produced the same results. He emphasized the importance of the blood distribution; the blood was not circulating equally in the body; it was stagnant here, and might be diluted elsewhere. This change in the distribution of the blood was shown in the active hyperemia during digestion and the consequent anemia in other parts of the body; therefore, the so-called anemia must be due to an unequal distribution of the blood in the body.

Dr. Henry Heiman emphasized rest in bed for those patients who were given digitalis. Morphine, digitalis, and salol were in his hands of paramount importance, and he had never had an untoward effect from their use. The administration of the coal tar products to children was not devoid of danger, and these patients should be watched with care; too large doses should not be given. Children had idiosyncrasies with opium as they had with the coal-tar preparations and analgesics. These were only antipyretics and analgesics. Hydrotherapy in children was of value; in the sthenic and strong children the cold baths were better borne than in the weaklings and acted as a stimulant; but in the asthenic type of cases the warm baths were to be preferred.

Dr. F. L. Wachenheim asked Dr. Grosse to explain how in the course of a few weeks the blood would show an increase of 3,000,000 erythrocytes, three-eighths of the total amount of red cells in the blood, when an individual went to Leadville. Did he mean to say that three-eighths of the total number of red cells were stored away in the body somewhere? In an individual of average weight there was twelve pounds of blood, and a large proportion of these erythrocytes made up the mass. Where could such a large proportion be stored? In Denver every healthy man had 7,000,000 erythrocytes; while with the cold water treatment there was but a difference of 500,000 at the most.

Dr. Sara Welt-Kakels said that antipyrin could be used with great benefit in whooping-cough, but it should be given in small doses in order to avoid the consequent cardiac depression. Venesection was an old method of treatment which, she believed, was coming into vogue again, although there was not much danger of the laity becoming very enthusiastic over it. Combe and other authorities had recommended venesection in certain cases. Most authorities, however, agreed that children would not stand the loss of blood very well.

Dr. Herman F. L. Ziegel said that the late Dr. Solly of Denver had proven that people coming to Denver from a low altitude became anemic with a reduced hemoglobin index in a short time. In some cases, however, altitude had a beneficial effect upon the anemias.

Dr. F. L. Wachenheim said that the observations made upon the inhabitants in the Alps showed that they had a red cell count of 8,000,000; while the inhabitants in the valleys had but 5,000,000. The number of red cells increased with elevation. An average healthy individual who ascended from a low level to 16,000 feet would have symptoms of anemia at once, such as dizziness, faintness, collapse, etc., but in the course of time the blood would get its recuperative powers and catch up.

Accidents of Decompression in Divers.—Stef. Zografidi has made a study of the accidents that happen among divers for sponges in the Mediterranean Sea on the north coast of Africa. There are three forms, a slight passing form of disease, an acute form which is frequent, and a sudden and severe form which results in immediate death. The main symptoms are intense pains throughout the body due to stretching and tearing of nerves by gas emboli; disturbances of sight and hearing, due to air bubbles in the cerebral circulation; and complete paraplegia due to congestion and hemorrhage of the spinal cord, followed by myelitis. When decompression is rapid the air that has been forced into the circulation is liberated and causes all these symptoms.—*Révue de Médecine.*

Ship's Nurses.—One of the great transatlantic steamship lines has added trained nurses to the medical personnel of its vessels. This opens a sea career for the trained nurse. Undoubtedly other lines will do the same, and the nurse will become as indispensable an adjunct to the first-class passenger vessels as the ship's doctor.—*New York State Journal of Medicine.*

GRAVE CHOREA AND ITS RELATION TO SEPTICEMIA.*

BY B. SACHS, M.D.,

NEW YORK,

ALIENIST AND NEUROLOGIST TO BELLEVUE HOSPITAL; NEUROLOGIST TO MOUNT SINAI HOSPITAL, ETC.

IT is my purpose in this paper to call attention to a grave form of chorea which I have had occasion to study of late years, more particularly in my service at Mount Sinai Hospital. The subject has excited my interest not only because of the rarity of the condition but chiefly because cases of this description can be almost instantly recognized as the expression of a severe general infection, and, furthermore, because the study of them throws considerable light upon the nature of all choreic disturbances. I disclaim at the outset every intention of establishing a new type of chorea.

Like epilepsy, chorea has become a generic term. The former may be the expression of injury to the brain, of inflammation in or near the cortex, of some intracranial neoplasm, and, for want of better knowledge, some of the cases of epilepsy are still ranked as idiopathic, but the number of these is growing smaller and smaller from day to day. In similar fashion we are still compelled to speak, in some instances, of idiopathic functional chorea, but there is little doubt that we shall soon be able to remove many, if not all, of these cases from the category of purely functional conditions. In other instances, the chorea may be dependent upon organic changes in the brain. This is unquestionably true of post-hemiplegic chorea in children or in adults. In still other cases chorea is the expression of a serious infection exerting its virulence chiefly upon the central nervous system. While septicaemic chorea is to engage our attention for the present, it will not do to generalize from these few cases and to infer, as a recent writer has done, that chorea—meaning chorea minor—is an infection "pure and simple." This position is untenable. We may admit that some cases of St. Vitus' dance may be of microbic origin. There is no more justice in claiming an infectious origin for all cases of chorea than there would be in claiming such for all cases of jaundice, although we know that jaundice occasionally accompanies a general pyemic infestion.

Infectious chorea is not a new subject. So long ago as 1872 Pianese claimed to have isolated a diplococcus and a diplobacillus from the cervical cord and the cerebellum of a patient who had died of St. Vitus' dance, and by inoculating cultures of these microorganisms into animals he claims to have produced chorea in them. The animals died "with muscular twitchings and convulsions," but whether this was actually a choreic disorder in any sense is open to discussion. The findings and the experiments of Pianese have not been substantiated by later observers. In 1894 Dana wrote a paper on the "Microbic Origin of Chorea." The patient was 34 years of age at the time of death. He had his first attack of chorea at 14 and had repeated attacks after that. The post-mortem findings included a chronic leptomeningitis of the convexity of the brain, hyaline bodies in the brain cortex, slight meningitis of the upper part of the spinal cord, and slight meningoencephalitis. Diplococci were found in the proliferating tissue between the meninges and the brain. Other authors have found staphylococci and streptococci in the blood of the heart of choreic patients, and a Russian, Preobajenski,* was able to get cultures of streptococci from the blood, the viscera, and from different parts of the central nervous system in a patient who died of a choreic disorder.† Naunyn, in 1888, found parasitic microorganisms in the inflammatory deposits of the mitral valve and in the pia. Steinkopf found various forms of bacilli in the spleen, the heart and the brain of choreic individuals. Berry claims to have found Weichselbaum's bacillus in the cerebrospinal fluid in a case of chorea. A special kind of streptococcus was developed by Wasserman and Westphal (in 1899) from the blood of a severe form of chorea and the same organism introduced into living animals caused the appearance of an acute polyarthritis. Rachmaninow reported two fatal cases of chorea in girls about 12 years of age, evidently due to some general infection; but the bacteriological proff is wanting. Heubner was the only one who succeeded in developing streptococci and staphylococci from the blood of a choreic patient taken during life, and by inoculation produced a streptococcic septicemia in mice; by inoculating a rabbit he produced swelling of the lower joint of the leg. But the very best work of this description was done by Cramer and Toebben, who succeeded in proving the presence of Gram positive cocci in the blood taken from one of their patients during life, and these bacteria were unmistakably streptococci. This case of Cramer and Toebben's is remarkably like one of those which I shall report this evening. These last named authors and Heubner are the only ones who have previously been able to establish the presence of septic organisms in the blood of the living subject suffering from choreic disorder. If found post-mortem the presence of streptococci or staphylococci may be subject to a different interpretation.

We are only now beginning to get positive evi-

*Part of a presidential address delivered before the New York Neurological Society, February 4, 1908. (At the time of reading the paper the writer had entitled it "acute toxic chorea"; the title of the paper has been changed in order to avoid any misunderstanding as to the object the writer has in mind.)

*Quoted by Cramer and Többen.

†In speaking of choreic delirium, Moebius and Kraepelin refer to the probable infectious origin of the condition. The latter considers the infection similar to that of acute articular rheumatism.

dence of the existence of an infectious form of chorea, but the evidence upon which this doctrine rests is still so meager that I trust the presentation of this subject will tend to promote renewed interest in every form of chorea. The most important step to be taken in every case of severe chorea, at least from a diagnostic point of view, is to make repeated blood examinations so as to prove the presence or absence of bacteria in the blood of the patient during the earlier stages of the disease.

If pathological and bacteriological studies suggest the infectious origin of certain forms of chorea, the clinical symptoms point with ever greater force to the existence of a special, infectious type of choreic disturbance. The clinical features of such a condition may be briefly summarized as follows: Septicemic chorea may occur at any period of life, although most of the patients hitherto observed have been youthful persons. One of Cramer and Toebben's patients was only seven years of age, the other thirteen. My patients were fifteen, eighteen and twenty-two years old. After a somewhat indefinite prodromal period of restlessness and slight twitchings, universal choreic movements of an extravagant type set in, which constitute the most prominent symptom of the disease. The jactations are so severe that the patients have to be restrained or have to be carefully watched over in padded beds. Erosions appear all over the body and particularly on the parts most apt to be rubbed or bruised by contact with the bedclothes and the bed posts. The erosions are found chiefly on the buttocks, the elbows and ankles. Speech is difficult at an early stage of the disease and later becomes impossible. This is due in part to the extreme choreic movements of the lips, of the tongue, and of the muscles engaged in the mechanism of speech, also to the accompanying mental change which may vary from mild stupor and apathy to a condition of active delirium.* The movements are lessened during sleep, but sleep is fitful and, as a rule, can be induced only by large doses of hypnotics and sedatives. After a period varying from one to two weeks, the patient passes from the state of continued restlessness into stupor and coma. After a further period of a few weeks, death supervenes. But I would not claim that a fatal termination is inevitable.† High fever is observed from the beginning to the end of the disease. A universal erythema bearing all the marks of a toxic eruption occurs in the earlier stage.

The salient features of this condition were brought out most clearly in the following two cases:

Case I.—On January 8, 1906, a young woman, F. S., 22 years of age, was admitted to the service of Dr. Rudisch, at Mount Sinai Hospital. The family history was negative and of the patient's past history we could only ascertain that she had had typhoid fever at six years of age, that she had never had either rheumatism or measles, pneumonia, or any other serious illness. There was no history, above all, of any cardiac or nephritic disease, and no history of any syphilitic infection. Her habits had been moderate. There had been no history of trauma. She had been married four years and had one child two and one half years old. There was no history of hemorrhages. We were told that the patient had always been of a nervous temperament. For the last six months she had not been feeling well but did not complain of any definite symptoms. Six weeks before admission to the hospital she fainted while ironing. Five weeks previous to her admission, it is stated, she noticed in the morning that the fingers of her right hand became swollen and twitched. This passed off as the day advanced. She complained of pain and paresthesia in the left hand before this attack, and since then the twitching would continue for a few days, and then subside. Three weeks before she was admitted to the hospital she passed through an acute illness of sudden onset consisting of chills, fever, and vomiting with streaks of blood. She was in bed for about three days. As we discovered later on, there was good reason to think that this acute illness was due to some uterine treatment which she received, the infection having been brought about through these manipulations. From this time on the twitching had gradually extended up the arm to the elbow, the patient continuing to be up and about until four days before admission, when the entire left side of the body and the head began to twitch violently. The movements grew more and more extreme until at the time of admission the arm and leg were constantly making the wildest sort of excursions. Her chief complaints on admission were the extravagant movements of the upper and lower extremities as well as of the head. When the patient was first seen by the writer on January 18, she presented typical choreiform movements of her left upper and lower extremities. These movements were so extravagant that it was impossible to make a physical examination, the patient throwing herself about violently. At times she would fall asleep for half an hour, when the movements would cease, but then would awaken and the choreiform movements would recur in full force. Her temperature varied between 101° and 103°. She took nourishment well, although there was great difficulty in feeding her. At this time she was mildly delirious, speech very indistinct, she was extremely peevish and fretful, and totally unable to understand questions put to her, and to answer them. Her condition remained practically the same for several days. The jactations, however, became so violent that the patient had to be restrained so as to prevent her from doing injury to herself. Her respirations ranged between 25 and 40, pulse between 125 and 130. The movements became more and more violent until on the evening of January 20 the patient fell into a deep sleep from which, as the notes state, she could not be easily aroused. Phlebotomy was done and about one ounce of blood was obtained. Examination of her heart showed that there was some pericardial friction, and there was a systolic murmur at the apex transmitted into the axilla. There was also marked accentuation of the second pulmonic. The coma became more intense, there was involuntary defecation and urination, and the pupils were contracted. For the first twenty-four hours after this deep sleep had set in she could occasionally be aroused; after that it was impossible to make any impression upon her. She developed a large bedsore over the sacrum, and the excoriations on the hand and abdomen, all of which were due to constant motion in bed. During this time a number of blood examinations were made. The patient remained in a comatose condition for eight days, the temperature varying from 102° to 104°, until death ensued on January 28, 1906.

I am indebted to the Pathological Department for reports on the blood cultures and upon the results of the post-mortem examination:

Blood Cultures—First Blood Culture: January

*Some of the cases described as chorea insaniens, maniacal chorea (Finny), etc., may be long to this group; in others, mental changes were associated with chorea of the chronic degenerative type.

†Ewald and Witte have reported a case of acute severe chorea (with recovery) due in all probability to intestinal infection, or to toxemia of intestinal origin.

20, 1906, showed *Staphylococcus aureus*, about three colonies to every cubic centimeter; 12 c.c. of blood was used.

Second Blood Culture: January 23, 1906, showed *Staphylococcus aureus* on all plates, about two colonies to the c.c., and in one of the flasks there were present streptococci besides staphylococci; 10 c.c. of blood were used.

Third Blood Culture: January 27, 1906, on a number of media there were found streptococci and staphylococci. In this blood culture streptococci predominated. On one of the agar plates there were 11 colonies of streptococci, and only two colonies of *Staphylococcus aureus;* 9 c.c. of blood were used.

Post-Mortem Examination—The patient died January 28, 1906, 2.40 A. M. Autopsy (limited) performed 19 hours post mortem.

Body—Poorly nourished. Several dried up blebs on both upper and lower extremities. No edema. No icterus. Petechiæ on ocular conjunctiva of both eyes. Large bedsore over sacrum.

Lungs—Negative except for congestion and subpleural emphysema.

Heart—Pericardium negative. Myocardium reddish-brown in color. Right side of heart practically negative. Left ventricle somewhat dilated. Mitral valve found retracted and chordæ tendinæ somewhat thinned. Both surfaces of mitral valve near the free border are small, short cauliflower vegetations. There are present also a few on the chordæ. No vegetations on aortic valve.

Liver—Large, congested, fatty and parenchymatous degeneration. Gall-bladder and ducts negative.

Kidneys—Capsules very slightly adherent. Markings very poor. Evidences of parenchymatous degeneration.

Spleen—Small, hard, reddish-brown in color. One small recent hemorrhagic infarct.

Pancreas—Very firm, rather small.

Uterus—External os hemorrhagic. Healing laceration extending from right side of os into the fornix.

Microscopical Examination—Lungs: Acute congestion, small area of bronchopneumonia. Liver: Acute congestion, perivascular cell necrosis. Marked parenchymatous, slight fatty degeneration. Spleen: Perisplenitis. Chronic interstitial inflammation, acute congestion, acute splenitis. Kidney: Parenchymatous degeneration. Vaginal wall: Purulent inflammation on surface. Thrombi in veins. Cervix uteri: Purulent inflammation.

Cultures—In pus from bedsore streptococci and staphylococci were found, the cultures from blood of heart and spleen were negative.

Bacteriological spreads from the pus of bedsore showed staphylococci and streptococci and Gram positive and Gram negative bacilli. The cultures showed only *Staphylococcus albus* and no *Staphylococcus aureus* or streptococcus. Streptococci were found in spreads made from spleen, but cultures from spleen and heart blood were negative.

Dr. Libman has been good enough to give me his opinion of the findings: "Evidently there was at first a systemic invasion of the *Staphylococcus aureus* with an establishment of an acute endocarditis. The port of entry for the infection was at the laceration of the cervix. This invasion was receding when apparently there was a secondary invasion of streptococci from the bedsore. The first infection cannot be attributed to the bedsore, which did not exist at the time when the *Staphylococcus aureus* was first found in the blood. Streptococci were found in large numbers in the spreads at the post-mortem examination. The fact that organisms could not be cultivated from the heart blood at the time of the post-mortem examination is to be explained on the theory that most of the bacteria lost their vitality during the time that the body lay in the ice-box before the post-mortem was made."

Case II.—R. R., admitted November 14, 1907, a school girl, Russian, fifteen years of age. Family history was negative. There was no history of tuberculosis or syphilis obtainable. The mother had two miscarriages some years after the patient's birth, none before. From the personal history it is only necessary to state that the birth was normal. Three months after birth the patient developed sores on the head and neck, but on no other part of the body, neither on the palms nor on the soles of the feet. She had had croup at one and one-half years of age; measles at three years; diphtheria at ten years; no sequelæ excepting enlarged glands on the right side of the neck. When eight years of age patient had an attack of "brain fever" in Russia, which lasted one week, during which time she suffered from headache, fever, and vomiting. Ice bags were constantly applied to the head at that time. No paralysis followed this illness, nor did she have any ocular paralysis at that time. The girl was well until two years ago and was regular in her attendance at school. Since that period, however, she has been complaining of pains in the soles of both feet and in the calves of both legs. The upper extremities were not involved. She had occasional sore throat and tonsilitis. All these disorders would point to a rheumatic infection. For the past two years she has also been complaining of eye symptoms, of constant headache, dizziness, and of seeing red balls of fire before the eyes. Glasses were fitted for this condition at a Williamsburg Hospital, after which there was some slight improvement in the symptoms. One year ago the same symptoms returned and she again had her glasses changed. About a year ago, while reading, she suddenly complained of seeing balls of fire before her eyes. She ran to her mother who caught her just about as she was to fall. At that time her mother noticed that her mouth was drawn to the left. She uttered a moderately low cry as though frightened, did not bite her tongue, but was unconscious for one-half hour, after which she gradually recovered. There was no paralysis at that time and no similar attacks up to the present illness, although the family physician told the mother that such attacks might recur.

Twelve weeks before her admission to the hospital it was noticed that the patient twitched her left fingers and hand constantly. This twitching soon spread to the whole of the left upper extremity and about two weeks later the left lower extremity was affected in a like manner. These purposeless movements have gradually spread over the entire body including the head and neck. The patient was constantly making grimaces of all sorts. Up to four weeks ago she could talk with ease, but since then has been unable to talk or to feed herself. She has been fed on fluids by means of a feeding cup for the past four weeks. She understands everything spoken to her. She had no fever, no ear discharge, no cardiac or nephritic symptoms. On further questioning it was elicited that the patient had had a severe attack of sore throat one month before the onset of the present illness. Her menstruations have been regular but accompanied by excruciating pelvic and abdominal pains.

Examination made shortly after admission showed that she was a large, well nourished, well

developed girl. Has adenoid facies. Careful examination of the chest and abdomen was precluded by the constant throwing about of all the extremities, trunk and head. These movements were distinctly choreic in character and involved the muscles of both halves of the body equally. Patient understands and tries to obey such commands as to show the tongue, to close the eyes, etc., but is prevented from doing so properly by these uncontrollable movements. She cannot speak. Seems to hear well. Takes her nourishment with difficulty, although the act of swallowing seems unimpaired. There is no rigidity of the neck.

A few days after admission she developed a generalized scarlatiniform rash on face, ears, extensor surface of upper extremities, on chest, especially about the breasts, over the abdomen, over the knees and calves. This eruption is distinctly erythematous, the skin being very dry and warm. Dr. Lustgarten, who was asked to see the patient, made the diagnosis: toxic erythema. The pupils and ocular muscles were entirely normal. The lungs were negative and of the heart's action the note was made: "It was rapid, regular, and of good force; the first sound soft and barely audible; no murmurs. Pulses regular and equal." The condition of the deep reflexes could not be determined on account of the choreic movements.

The patient remained practically the same during her first week's stay in the hospital. The movements were temporarily controlled by hyoscin. There was some tenderness over the tip of the left mastoid, but Dr. Gruening, who was asked to see the patient, was of the opinion that there was no ear condition which could be held in any way responsible, either for the chorea or for the infection. A large abrasion had developed over the left elbow, and the temperature which since admission had varied between 101° and .04°, now rose to 106.8°. Repeated blood cultures were made and the results were entirely negative. From this time on the patient's condition remained practically the same. Under treatment the choreic movements became at times a little less intense but could not be well controlled by hyoscin or other drugs. On November 20 the choreic movements were distinctly lessened and the patient passed into a stuporous condition, from this into a state of coma with stertorous breathing, with high temperatures and with no further change in her condition until death ensued on November 27.

In this case the following reports were submitted by the Pathological Department:

First Blood Culture: November 15, 1907; 5 c.c. of blood were used; no bacteria were found.

Second Blood Culture: November 17, 1907; 15 c.c. of blood were used with a negative result.

Third Blood Culture: November 26, 1907; 15 c.c. of blood were used with a negative result.

The media in all these blood cultures consisted of glucose bouillon, both of these alone and with serum and glucose sugar and glucose serum agar. In the last blood culture all of the study was carried on anaërobically. The examination of the cerebrospinal fluid was negative.

Blood serum obtained by venesection just before death was inoculated into a rabbit by Dr. Strauss, 5 c.c. on one day and 8 c.c. on the following. No effect; rabbit lived two months. Second rabbit inoculated about the same time with cerebrospinal fluid obtained post mortem, 5 c.c. one day and 8 c.c. the following; intravenous injection, produced likewise no effect on the rabbit, it being still alive. Anaërobic cultures made of this cerebrospinal fluid show no growth.

The post mortem was made twenty-one hours after death, by Drs. Libman and I. Strauss. At that time a blood culture was made, using 2 c.c. of blood obtained from the heart. Streptococci were found in this culture. This streptococcus was found to be quite virulent for mice, and also for rabbits when inoculated intravenously. Joint changes were found only in the first animal inoculations. In that instance both knee-joints contained a moderate amount of clear fluid, all the joint surfaces showed no changes and cultures of the blood remained sterile. The streptococci differed culturally from the streptococci ordinarily encountered.

Dr. Strauss summarized conditions of the organs as follows:

Liver—Shows marked congestion and extensive parenchymatous degeneration with fatty infiltration.

Spleen—Shows very marked congestion and hemorrhage. No enlargement of Malpighian corpuscles.

Lungs—Marked congestion with hemorrhage into some of the alveoli.

Kidneys—Excessive congestion and acute nephritis.

Ovaries—Negative.

Heart—Verrucous endocarditis; slight evidence of parenchymatous change in the muscles and likewise one area of small round-cell infiltration found in one section, the infiltration being in the intermuscular fibrous tissue.

Brain—Section of post-central, precentral convolutions show degenerative changes in the ganglion cells, like those discovered as following upon acute toxic conditions. Similar changes are present in the Purkinje cells of the cerebellar cortex and in the anterior horn cells at different levels of the spinal cord. There is disappearance of the Nissl bodies, displacement of the nucleus in other cells, shrinkage of the nucleus, and in some total disappearance of the same. The contour of the cells is irregular, and in some instances cells appear to be swollen and stain diffusely.

Dr. Libman's summary is as follows: "The pathological changes in this case point to a marked general infection. There is a recent verrucous endocarditis, apparently due to bacteria that cannot be grown by ordinary culture methods. The streptococci found at the post-mortem examination must be looked upon as a post-mortem invasion, for the last blood culture taken only a few hours before death revealed no bacteria."

To these cases which have been given in full detail, a number of other fatal cases might be added from my own experience in hospital and private practice.

I might refer to a young girl of twelve, whom I saw about eighteen years ago, who had passed successfully through a number of severe attacks of chorea minor, but finally developed an attack with high, incessant choeric jactations, marked cardiac disturbance, ending, as I thought at that time, in death from exhaustion after a period of about two weeks.

Another case was that of a girl, R. B., eighteen years of age, who was admitted to my ward in the hospital, April 16, 1905, dying May 4, 1905. Her clinical symptoms were entirely like those of the two cases which I have detailed. She exhibited constant and universal choreic movements following upon what appeared to be an ordinary attack of chorea minor which was developed when she heard

the startling news that one of her brothers had been killed. She had never had St. Vitus' dance before this, and the movements after two weeks became so severe that she could not be controlled at home and sought admission to the hospital. She could not speak, although for a time she seemed to understand what was said to her. She gave assent when her name was mentioned, but beyond that we could not get any expression from her indicating that she was conscious of her environment. From April 20 on she began running irregular, remittent temperatures, suggesting the curve of a septic fever. She developed erythematous patches all over the body, but particularly in the face. She had to be fed through a cup or a tube. The choreic movements became more and more marked, until she passed from the condition of choreic restlessness into that of stupor and coma, and died about one month after the onset of the first choreic movements and eighteen days after her admission to the hospital. In this case no autopsy could be obtained.

It is useless, however, to increase the number of purely clinical histories. I prefer to base my conclusions upon the two cases with autopsy, and upon the bacteriological studies made in these cases. Reviewing this experience in an impartial spirit, the conclusion is inevitable that the grave chorea herein described was due in Case I to a general septicemia caused by the invasion of staphylococci, and in Case II to some organisms not yet determined. If we knew more about the elusive microbe of acute endocarditis we might have been able to shed more light on this case. The search for a single specific organism as the cause of chorea seems to me fruitless, and in view of what has already been discovered, entirely illogical. Some forms of chorea are evidently the expression of an acute general infection. There may be a number of different microbic agents giving rise to this condition, but it seems reasonable to suppose that certain bacteria have a special predilection for the motor neurons, while others exert their baneful influence over the sensory elements of the central and peripheral nervous system. Whether the infection be due directly to those microorganisms or to a toxin formed by them, it is not my province to decide. Other questions press for more immediate consideration.

First of all, is chorea the only form of motor disturbance, and is it the only distinctly cerebral symptom accompanying virulent forms of septicemia? Although the bacteriological evidence on this point is still incomplete, I believe that we shall find that acute grave delirium with its marked motor disturbance, some of the virulent forms of meningitis, possibly some of the post-puerperal forms of encephalitis, will be found to be allied, pathologically at least, to toxic chorea. Only a few weeks ago I was asked to see in consultation, a man of forty who had been well until he suddenly began to complain of slight ear symptoms with intense headaches and chills. In less than twenty-four hours there was loss of consciousness with incessant motor activity so that the patient could not be held quiet for an instant. Within forty-eight hours from the time of onset these agitations gave way to complete coma, and after a few hours more death resulted. Lumbar puncture was done revealing the presence of the *Streptococcus mucosus capsulatus* which Buerger and others have shown to be one of the most virulent forms of streptococci. The port of entry for the virulent organism in this case was, no doubt, the ear which had become diseased after what was supposed to be an ordinary attack of influenza.

Referring once more to the choreas as such, the question arises whether there is, after all, any relationship between what we have called septicemic chorea and ordinary chorea minor. The same nerve elements, assuming for the time that they are the motor neurons in the cortex and elsewhere, are affected, in the one case possibly in a purely functional manner as a result of exhaustion, in the other case by the poison acting upon these same neurons. The parts affected may be the same in both diseases, but the disease process would seem to me to be an entirely different one. Nor can one claim that septicemic chorea is merely an intensification of the morbid process giving rise to chorea minor. To my way of thinking a new and independent infection has been, or may be, superimposed, upon a preceding chorea minor. The nerve elements involved in the latter fall victim most easily to the influence of a toxin circulating in the system, and in this way we may account for the fact that in several of the cases reported mild attacks of chorea minor have preceded the grave attack culminating in death. We must not overlook the fact, furthermore, that the constant abrasions of the skin brought about by the frequent movements of the choreic patient yield easy and innumerable points of access for the invading organisms. We can also understand that grave chorea may be developed in an individual who has never been subject to choreic movements of any sort: but I shrink from mere theorizing.

We may infer from the previous review of the subject and from the arguments just adduced, that the bacteriological origin of chorea minor has not been firmly established. Bacterial cultures obtained post mortem cannot be accepted as satisfactory evidence of a bacteriemia existing during life. Taking only those cases into consideration in which the microorganism was found in the blood during life, we see that we have only one case of Heubner, one case of Cramer and Toebben, and the first of the two cases reported this evening, which prove beyond a doubt the existence of a septicemia in patients afflicted with acute grave chorea. In some of these cases streptococci have been found, in other staphylococci, and it is more than likely that in such a case as the second one reported this evening some other organism not yet determined will be found to be the cause of the disease. There is no reason to be astonished at the diversity of these findings, and there is no reason to expect that any one organism should be responsible for such a condition as denoted by the term septicemic chorea. If objection were to be raised to this term and the question should be asked why we speak of infectious or toxic choreas at all, I would say that we have no choice in the matter, and for the present must speak of these conditions in the term of the most prominent clinical symptom, but I have no doubt that in years to come we shall have further data and shall be able to speak of these same conditions as a general streptococcic or staphylococcic (or some other bacterial) infection or toxemia accompanied by choreic movements, but until the pathogenesis of this condition is more clearly and safely demonstrated, the only rational course to pursue is to retain such a term as septicemic chorea for the convenient grouping of cases allied to one another, symptomatically and etiologically.

It is manifestly impossible to close a discussion of this subject without endeavoring to classify the various forms of chorea, omitting from consideration the cases of post-hemiplegic chorea which are due to a gross cerebral lesion. We have, first, a not

inconsiderable percentage of cases of chorea minor which have, up to the present time, not yielded the slightest evidence of being due to an infection, and which we must, until further proof is forthcoming, consider as being due, for want of a better term, to an exhaustion of the nerve elements.

Next come the cases associated with endocarditis, with rheumatism, with fever; on the whole, a more severe group of cases than the first. Thayer's analysis of eight hundred and eight cases is of great interest. Some day when bacteriologists will have discovered the microorganisms of acute articular rheumatism and of the various types of infectious endocarditis, we shall have more light on this group of cases of chorea.

Chorea gravidarum constitutes a third distinct group, although it is possible that this may be due to some poison circulating in the system; just as Ewing, Williams and Strauss have shown that the vomiting of pregnancy is probably the expression of a toxemia; and if such patients give the history of having had previous attacks of chorea minor in early life, it simply goes to prove that the centers for choreic movements are especially prone to the influence of such poisons.

A fourth group would be the senile choreas, and possibly some of the so-called chronic choreas associated with marked arteriosclerosis, with nephritis, and with other degenerative changes. Whether or not these are toxic in character must be established by later researches.*

Lastly, we have the septicemic choreas which have been the main subject of this study, and for these we can at least claim that the microbic origin of the disorder has been established beyond reasonable doubt.

If we have had to shift our point of view from the consideration of symptoms to the consideration of general infective processes, we are keeping pace, it seems to me, with the advance in clinical medicine. The study of toxemia and of general infection looms up big in the future study not only of chorea, but of syphilis of the general nervous system, in the study of meningitis as well as in the researches now in progress on acute anterior poliomyelitis.

The prognosis of septicemic chorea would seem to be extremely grave, but I am not willing to believe that every such case must necessarily prove fatal.

As far as the treatment is concerned, it has been unavailing to the present time. Salicylates, sedatives, hypnotics, and the usual forms of hydriatric treatment have been employed. The good results that have been obtained in other severely toxic and infectious disorders by the use of appropriate antitoxins, leaves us some hope for the future. Meanwhile we must endeavor to eliminate, if possible, toxic products circulating in the body; the wisdom of such a procedure was shown in the recently reported case of Ewald and Witte.

THEORETIC CONSIDERATIONS RELATIVE TO IMMUNIZATION BY MEANS OF THE TUBERCLE BACILLUS AND ITS PRODUCTS.*

By WILLARD J. STONE, M.D., Toledo, O.,
and
E. C. L. MILLER, M.D., Detroit, Mich.

The problem of immunization in tuberculosis by means of the germ and its products has been prominently before the profession ever since Koch[1] in 1890 introduced his bouillon filtered product (old tuberculin) as a remedy for the treatment of the disease.† The elapsed years have, however, brought forth evidence to show that its sphere of usefulness is much more limited than originally believed. The original doses were probably too large and progression in dosage was made too rapidly, with the result that severe reactions were common. Immunization experimentally could, however, be produced so that animals failed to react to many times the original dosage. It was soon realized, however, that such immunization did not protect the animal against the invasion of the germ itself.

The old tuberculin contains the products elaborated by the germ when grown on glycerin-bouillon which is afterwards concentrated by evaporation to one-tenth the original volume. The germs are then removed by filtration. The filtrate, which is used, contains the products of the germ soluble in water and glycerin more or less modified by heat. Purified tuberculin is old tuberculin purified by precipitation with alcohol.

The bouillon filtrate of Denys[2] also contains the products of the germ when grown on bouillon. The germ bodies are removed by filtration. To the filtrate one-fourth of one per cent. of phenol is added and allowed to stand until the slight coagulation thus formed has settled out, when it is ready for use. This bouillon filtrate (B. F.) contains the water-soluble products of the germ *unchanged by heat*, and in this respect differs from the "old tuberculin." Its action is, however, practically the same as the old tuberculin and the purified tuberculin. These three products, old tuberculin, purified tuberculin, and bouillon filtrate, contain the toxic products of the germ, but probably none of the constituents of the germ body. A patient when injected with either of them shows increased agglutinative and opsonic power toward the germ. The protective influence of any of the filtrate products is largely antitoxic and not bactericidal. It would, therefore, seem that

*Read before Northwestern Ohio Medical Association, Toledo, O., December 10, 1907.

†The early attempts at immunization by Cornil, Leloir and Babes in 1883, Charrin in 1885, and by Daremberg in 1887, as well as by Hammerschlag, Jeffries, Hueppe and Scholl, Trudeau, and others, while interesting from the historical standpoint, do not require review for the purpose of this article. The early history of tubercle immunization is fully given in von Ruck's article in the Medical Record, January 20, 1906.

the use of the filtrate products would bring more benefit in cases suffering from pure tuberculous toxemia. Toxemia is not, however, a prominent feature of uncomplicated tuberculosis, at least in early stages. How important the toxic feature becomes in advanced cases, due to the absorption of the products of the tubercle bacillus in the body, remains to be settled. Without secondary organisms (influenza-bacilli, pneumococci, staphylocci, and streptococci) it is probable that toxic features with softening and dissolution of tissue, as we now understand the process, would be a much less important factor in the course of the disease.

All sorts of methods, mechanical and chemical, have been tried to separate from the germ body the poisonous properties of the cell, in the hope of inducing by injection in the treated individual antitoxic, bactericidal, and antiendotoxic immunity, but with varying degrees of success. Von Ruck[3] in 1896 washed the bacilli upon a filter until he had removed all water-soluble proteids, then extracted the fats, after which the germ residue was taken up in water. This watery extract, he claims, contains the specific immunizing substance of the cell body, the hindering substance to its liberation having been removed by the extraction of the fats. Von Ruck has had a most extensive experience in the past eight years in the employment of this bacterial product in suitable cases and his reports show a high percentage of recovery. Von Behring[4] evidently had the same object in view when he presented his work in 1898. He washed the bacilli, then extracted the fats, and again extracted the residue in glycerin and water at a temperature of 150° C. in the autoclave. Such a degree of heat, as Von Ruck and others have noted, must have modified chemically, if not destroyed, the resulting toxin. It has never been used clinically, to our knowledge. Von Behring's latest contribution to the subject was before the International Congress for Tuberculosis (Paris, 1905). He believes that the curative, immunizing property is inherent in the germ body, and that it can be obtained after extraction with water, then with ten per cent. solution of sodium chloride, and finally with alcohol and ether. The remaining residue is reduced to powder and injected subcutaneously. He calls this curative product T. C.

Koch[5] in 1897, by grinding masses of the dried germ for hours in a mortar, found that he could break up, more or less, the cell body. When reduced to a fine powder, distilled water is added and the solution centrifugalized. This throws down a cloudy mass, the supernatant fluid containing the water-soluble constituents (Tuberculin oberst, T.O.) being discarded, as it produces practically the same effect as the old tuberculin. The residue (Tuberculin rückstand T. R.) is ground and reground until all goes into solution. Koch claimed to possess in this product not only the properties of the cell, which would when injected bring about immunity against the bacillus itself, but also immunity against its toxin. He, in fact, succeeded in immunizing guinea pigs so that at later periods they were not susceptible to the injection of virulent cultures. *In the T. R. at least part of the water-soluble constituents of the cell are removed and discarded.*

In the next product to be described, the so-called Bacillen Emulsion (B. E., Koch, 1901[6]), the dried germs of known virulence are ground and reground for weeks, after which physiological salt solution is added and the suspension set aside to sediment, so that any particles of germ substance not completely disintegrated may be deposited. The resulting supernatant suspension, to which an equal amount of glycerin is added, is standardized so that it contains five mg. of ground germ substance per c.c. After standing for two or three months, and after testing by guinea pig inoculations to be certain that it contains no living tubercle bacilli, it is ready for use. *The B. E. may be said to possess all of the properties of the cell body itself.* Koch recommended this for treatment of patients as superior to T. R. because when injected into animals it produces a higher agglutinative power.

In attempting immunization it may be supposed that the effort should be directed in any given case toward not only the products elaborated by the germ, the toxins, but against the endotoxins of the cell body as well. This has been common knowledge for years, and was the idea Koch had in mind when he produced the T. R. and Maragliano,[7] his liquid F. (the filtrate product of tubercle bacilli on glycerin-bouillon to which has been added equal parts of watery tuberculin), and his Bacillary Pulp (germ bodies ground to destruction with clean, dry sand: cold distilled water is added and the product filtered). This cell filtrate, which is sterile, is supposed to contain all the water-soluble constituents of the germ body unaltered by heat. When prepared in the proportion of ten parts of water and one of bacilli by weight it is ready for use in combination with the bouillon product (Liquid F.) to produce immunity in cows by repeated injection. After the serum of the treated animals reaches 1,000 antitoxic units per c.c. it is used for therapeutic purposes. He endeavored to bring about passive immunity through the medium of bodies elaborated in animal serum.

Maragliano's work has been carried on in this country during the past two years at the Henry Phipps Institute, Philadelphia. Maragliano has reported many hundreds of cases cured or improved under the use of this serum. At the Henry Phipps Institute the results have been variable and the men who have used it are divided as to its efficacy.

The bacillary pulp of Maragliano probably contains more of the cell endotoxins, despite the fact that filtration of the suspension is employed, than any other product except B. E. The weak point, it seems to us, in his work lies in the unfortunate fact that his antiserum, however successfully made, was in the body of the animal, not in his patient, and experience has shown that such immunity cannot, for the tubercle bacillus, be successfully transferred. Maragliano has shown that in antitoxic value the serum of man is much greater than the serum of cow, goat, or horse, but in antibacterial power the serum of the calf, cow, and swine is greater than that of man. It would, therefore, appear that the attempt should be made in man to first increase the antibacterial value of the serum, since normally this value is lower than the relative immunity existing toward the products of the germ. In the early stages of tuberculosis, as before mentioned, the toxic effects are probably slight and in favorable cases the toxin is probably largely neutralized by the antitoxins elaborated in the blood serum under the stimulating effect of the absorbed toxin.

Vaughan and Wheeler[8] have more recently directed attention to the split products of the tubercle bacillus. They used a nonvirulent strain, first extracting the fats and waxes of the cell body with alcohol and ether; the remaining cellular substance is covered with absolute alcohol (two per cent. alkaline with sodium hydroxide) and treated for an hour at the boiling point. After three such extractions it is found that the substance is split into a portion soluble in the alcohol (designated the "cell poison") and an insoluble portion (the "cell residue"). "The 'cell poison' when given to healthy ani-

mals in very small repeated doses has no visible effect, but when given in very small doses to tuberculous animals it intensifies the tuberculous process and in all cases the treated animals die before the controls." The "cell residue" is the nonpoisonous group. It has the apparent effect of sensitizing guinea pigs to the tubercle bacillus. They conclude that if patients can be sensitized to the bacillus as well as the guinea pigs, "cell residue" may be of service in limiting the spread of an early localized tuberculosis; but, on the other hand, it may be a dangerous remedy when large numbers of bacilli exist in the body, since the specific bacteriolytic ferment produced under the influence of such a sensitizing substance may be sufficient to liberate from large numbers of bacilli a dangerous amount of toxin. The more the matter is considered the more do we believe, except in rapid fulminating types of phthisis or miliary tuberculosis, that pure tubercle toxemia is comparatively unimportant.

Vaughan and Wheeler have also obtained from the bouillon in which the germs were grown two split products, one poisonous ("precipitate poison") and one non-poisonous (the "precipitate residue"). The "precipitate poison" has a similar poisonous effect upon animals to the "cell poison." The "precipitate residue" sensitizes guinea pigs to the tubercle bacillus in much the same way as the "cell residue." They express the belief that "no preparation from the tubercle bacillus should be used in the treatment of tuberculosis until the poisonous cell proteids and the poisonous proteids in the media for the growth of the germ have been removed." The experience of many who have worked with the products of the tubercle bacillus and with certain constituents of the cell body (such as T. R.) as a means of inducing relative immunity does not correspond with this view; that is, from the clinical standpoint in selected cases not overwhelmed with extensive lesions.

Rosenau and Anderson,[9] who have done so much work on the problem of hypersusceptibility, have expressed the belief that resistance to disease may be largely a matter of hypersusceptibility at some time, and that the "phenomenon of hypersusceptibility to certain bacterial proteids is followed by a definite immunity against infection by the microorganism." They have also succeeded in sensitizing animals, by most minute doses, to other proteids, such as hemoglobin, egg albumin, and peptone. Such work on the bacterial proteids may have the greatest bearing upon the whole problem of bacterial therapy. When a sufficient sensitizing quantity of any strange proteid has been given to an animal a definite period must elapse between the first and second injection, otherwise symptoms of collapse supervene more or less rapidly and many of the animals die. They have shown that subsequent injections, properly given as to time, bring about with certain germs (colon, typhoid) immunity to the infection. This phenomenon is not universally true, however, since in the case of the anthrax bacillus immunity does not follow hypersusceptibility to its bacterial proteid.

To return to the tubercle bacillus, many other tuberculin preparations have been used in the treatment of the disease, but they all fall, theoretically at least, into one or the other of the two classes used below.

TUBERCULINS

1. Toxic Media Products...	Old Tuberculin, O. T. Koch. Bouillon Filtrate, B. F. Denys. Purified Old Tuberculin.	Productive of Antitoxic Immunity.
2. Endotoxic Cellular Products...	New Tuberculin, T. R. Koch (part cellular product) Bacillus Emulsion (total cellular product).	Productive of Antibacterial Immunity.

Practically all of them mentioned in the above classification, when suitably used, raise the agglutinative and opsonizing powers of the blood serum.

In any given case the difficulty lies in deciding which preparation had best be used. We refer to early nonfebrile cases or to favorable cases not manifesting a temperature of over 99.5° F. Denys and Trudeau have used extensively the B. F.; von Ruck, the watery extract; many others, including Wright, the T. R., while others have used the B. E. Trudeau,[10] and others have called attention to the fact that "the method of Wright takes no account of habituation by progression in dosage and the production of tuberculin immunity, but merely aims at keeping the patients' opsonic index as high as possible by properly spaced and indefinitely repeated doses of about the same amount of tuberculin." Trudeau believes that the proper way to produce tuberculin immunity is to very gradually increase the dose, if possible, to from one thousand to ten thousand times the dose used at the commencement of treatment. This should be done by using minute doses and very gradually increasing in order to avoid marked reactions (of which, from the opsonic standpoint, prolonged negative phases are to be considered a part) or any disturbance of the patient's health. Trudeau has mentioned the use of the B. F. and B. E., but never, to our knowledge, a combination of the two.

The part played by the opsonins in the production of immunity is but one of the factors probably necessary. We express the belief that no one of these products mentioned possesses all of the properties desired in the production of immunity; that is to say, the products elaborated by the germ as well as the entire cell body. The belief has been expressed in previous pages that, theoretically at least, the antibacterial elements (the constituents of the cell body) are more necessary in the early stages of the disease than the antitoxin elements (the media products of the germ).

This, of course, is more or less speculative, although considerable experimental data gives ground for this belief (see Maragliano).

One of us has had a certain measure of success through the use of a combination of T. R. and old tuberculin in the treatment of incipient cases, with results apparently better than he has previously been able to obtain by using the T. R. alone. The number of cases is, however, too small to draw even tentative conclusions. Two recent cases, typical of others, will be briefly mentioned. The first patient gained in weight from 107 to 123 pounds in two months; the few tubercle bacilli present in the beginning disappeared (probably in this case pure tuberculous toxemia); the secretion of HCl, which was in the beginning so diminished as to cause constant vomiting after taking food, approached the normal, and the vomiting ceased. The second patient, two months ago generally asthenic and bedridden, although the amount of lung involvement was slight and might be called incipient, has so much improved that whereas in the beginning she reacted severely to 0.5 mg. old tuberculin, she now withstands 0.5 mg. T. R. and 1.0 mg. old tuberculin in combination without temperature reaction or exaggeration of moist sounds, and for the past month has markedly gained in weight and is able to exercise in the open air without rise of temperature. Of course, such results are not uncommon in favorable cases with any form of treatment. We do not ascribe the benefit to the inoculations alone.

It seems to us, however, that possibly better results might be obtained by using a combination of

the B. E. and B. F. in treatment; that is, by beginning with small doses of, say, one ten-thousandth mg. of B. E. in combination with one ten-thousandth mg. of the B. F. and increasing the doses as rapidly as the clinical evidence warrants up to many thousand times the original dosage of each.

The following solutions will be employed, numbered one to ten each, of the Bacillen Emulsion and Bouillon Filtré. The dose to be given according to tolerance once or twice weekly will be 0.5 c.c. of solution No. 1 B. E. in combination with 0.5 c.c solution No. 1 B. F.

The progression in dosage will be made as follows: Ten injections in combination of Solutions No. 1, increasing gradually during the series of ten injections by tenths of a cubic centimeter (from the original dose 0.5 c.c. each of Solutions B. E. and B. F.), so that upon the completion of the series of ten injections one c.c. each of B. E. and B. F. is given, thereby approximating the initial dose of the next solution.

Then ten injections of Solutions No. 2, likewise increasing by tenths of a cubic centimeter (from the original dose 0.5 c.c. each of Solutions B. E. and B. F.), and so on until ten doses of Solutions No. 10 have been given. It will thus be seen that from six months to one year will be required for the complete series.

In computing the solutions each cubic centimeter of marketed B. E. suspension was, according to the standard usually adopted, figured to contain 5 mg. ground germ substance, and each cubic centimeter of marketed B. F. was figured to contain 1000 mg. of toxin. It seems to us that any method in which a certain number of drops are to be measured to obtain the dose desired is open to objection in dealing with such small quantities, since the size of the drop depends so much on the diameter of the dropping end. In measuring the dose for injection a syringe accurately marked in cubic centimeters should be used.

BACILLEN EMULSION.

(Solid Substance not Liquid Measure.)

Each 0.5 c.c. of Solution			*Standard Suspension*
No. 1 contains	$\frac{1}{10{,}000}$ mg.	=	$\frac{1}{50\,000}$ c.c.
" 2 "	$\frac{1}{5{,}000}$ mg.	=	$\frac{1}{25{,}000}$ c.c.
" 3 "	$\frac{1}{2{,}500}$ mg.	=	$\frac{1}{12{,}500}$ c.c.
" 4 "	$\frac{1}{1{,}000}$ mg.	=	$\frac{1}{5{,}000}$ c.c.
" 5 "	$\frac{1}{500}$ mg.	=	$\frac{1}{2{,}500}$ c.c.
" 6 "	$\frac{1}{250}$ mg.	=	$\frac{1}{1{,}250}$ c.c.
" 7 "	$\frac{1}{100}$ mg.	=	$\frac{1}{500}$ c.c.
" 8 "	$\frac{1}{10}$ mg.	=	$\frac{1}{50}$ c.c.
" 9 "	$\frac{1}{5}$ mg.	=	$\frac{1}{25}$ c.c.
" 10 "	$\frac{1}{0}$ mg.	=	$\frac{1}{5}$ c.c.

BOUILLON FILTRE.

(Liquid Measure.)

Each 0.5 c.c. of Solution			*Standard Filtrate*
No. 1 contains	$\frac{1}{10{,}000}$ mg.	=	$\frac{1}{10{,}000{,}000}$ c.c.
" 2 "	$\frac{1}{5{,}000}$ mg.	=	$\frac{1}{5{,}000{,}000}$ c.c.
" 3 "	$\frac{1}{2{,}500}$ mg.	=	$\frac{1}{2{,}500{,}000}$ c.c.
" 4 "	$\frac{1}{1{,}000}$ mg.	=	$\frac{1}{1{,}000{,}000}$ c.c.
" 5 "	$\frac{1}{500}$ mg.	=	$\frac{1}{500{,}000}$ c.c.
" 6 "	$\frac{1}{100}$ mg.	=	$\frac{1}{100{,}000}$ c.c.
" 7 "	$\frac{1}{10}$ mg.	=	$\frac{1}{10{,}000}$ c.c.
" 8 "	$\frac{1}{0}$ mg.	=	$\frac{1}{1{,}000}$ c.c.
" 9 "	10 mg.	=	$\frac{1}{100}$ c.c.
" 10 "	100 mg.	=	$\frac{1}{10}$ c.c.

It will be noted that the progression in dosage is more rapidly made in the solutions of B. F. than in the solutions of B. E., since it has been shown that B. E. habituation takes place more slowly and that there is more tendency to reaction. Of course, slight reactions will occur occasionally in the most carefully conducted case. The aim should be to increase the patient's tolerance to just short of the amount required to produce reaction. If signs of reaction occur, great care should be exercised in repeating the dose until evidence of reaction has disappeared.

It is proposed during the next two years to treat a series of cases after this method. One of us will have supervision of the preparation of the material and the other will watch the results clinically. Nothing new, except the method of its application, is ventured in the method suggested, it being merely what Koch had in mind when he developed the T. R. and the B. E., and also Maragliano when he used for immunization in the cow his Liquid F. and Bacillary Pulp in combination. We believe, however, that all of the preparations named (and there are many others not mentioned for the purpose of this article, such as Büchner's Tubereulo-plasmin, Landmann's Tuberkulol, etc.) lack when used alone one or other of the qualities desired when attempting to produce immunity by bacterial therapy. Autoinoculation in tuberculosis from the effect of exercise and the raising of the index thereby, together with other equally interesting features of the tuberculous process and its relation to resistance, will be fully considered in the work to be undertaken.

HOW MUCH GYNECOLOGY AND ABDOMINAL SURGERY SHOULD THE GENERAL PRACTITIONER OF MEDICINE KNOW?†

By W. A. NEWMAN DORLAND, A.M., M.D.,
PHILADELPHIA
ASSISTANT INSTRUCTOR OF OBSTETRICS, UNIVERSITY OF PENNSYLVANIA.

Two remarkable experiences within the past six months have forcefully brought to my attention a matter which fifteen years of post-graduate teaching in the Philadelphia Polyclinic had already strongly impressed upon me, namely, the importance of a general knowledge of pelvic anatomy and pathology for every man who attempts the practice of medicine. Especially do I emphasize the value of this knowledge of the pelvis and its viscera to those who are called upon to pursue their profession in country districts and smaller villages and hamlets where immediate access to a specialist and surgeon cannot be had, and a delay of some hours must ensue before radical help can be obtained. Frequently under such circumstances to recognize the condition in an urgent case and to know what to do means all the difference between life and death. In other words, my plea to-day is for the cultivation to the utmost of the diagnostic ability of each and every medical man in the country in preference to the acquiring of an extensive knowledge of surgical and laboratory technique, valuable as this may be in its proper place.

It was, I believe, my distinguished teacher, the great surgeon, Dr. D. Hayes Agnew, who formulated the axiom: "A good physician may make a good surgeon, but a good surgeon must be a good physician." I have always held that it is a deplorable mistake for a young man just graduating from a medical college or from his post-graduate hospital interneship to enter immediately upon a career as a specialist in any line of medical or surgical work. Much better is it for him to acquire first a practical experience in general medicine, together with a knowledge of how to deal with men, and then with this substantial foundation to insure success, to grow gradually into his chosen line of specialization. By adopting such a course he is broadened mentally, and his view of things as he sees them is deeper and larger than it would be had he limited his experience and thereby acquired the narrowness and mental strabismus that invariably results from an early specialization of one's work.

A few years ago I heard the distinguished Philadelphia Shakespearian scholar, Dr. William Henry Furness, in a notable address before the University of Pennsylvania and its friends, advocate that the well-read man is one who has a general smattering of information. I believe this to be true in a literary sense or from the standpoint of social cultivation, but it will be well for us to bear in mind that often from a professional point of view "a little knowledge is a dangerous thing." Therefore, while urging the value of a general knowledge of pelvic and abdominal pathology to every medical man, I have repeatedly recoiled and mentally protested upon hearing an able abdominal surgeon, carried away by his enthusiasm during the brilliant performance of a difficult celiotomy, remark to a class of post-graduate students: "Any one of you should be able to perform an abdominal section." This is not true. If each and every medical man in this broad land of ours should attempt to perform an abdominal operation of so great gravity as this I venture to affirm that the mortality records of that serious surgical undertaking would not be as it is now, one-half of one per cent. or less for a general laparotomy and one or two per cent. for hysterectomies and the graver abdominal operations, but would reach five or even ten per cent. or more for all abdominal sections. Such a course would work a twofold injustice. The operation itself and the surgeons as a class would be discredited in the eyes of the public, and the unfortunate victims of this necessarily imperfect surgery would be wronged beyond the possibility of correction.

It is not an impossible picture I am painting. Not so very long ago an aggressive, loud-voiced physician from a New England State remarked to me that he had then, when just completing a three-weeks' post-graduate course in gynecology, seen at first hand an even dozen abdominal sections, and that it was his intention on returning to his home the following week to do two similar operations upon patients of his. He further asked me whether I did not think he was able to do such work after that experience. I replied that that was a matter for him to decide for himself, but that I had *assisted* in over two hundred sections before I attempted my first operation.

"Experience worketh caution," and when it has been your unfortunate lot to see, in the hands of able surgeons, a woman bleed to death upon the operating table from a punctured cavernous fibroma of the uterus without the possibility of arresting the hemorrhage; a bladder torn almost entirely from its base; a dislocated ureter completely severed or enclosed in a hysterectomy ligature; a bladder adherent to the umbilicus and displaced by massive pus-tubes opened with the first incision; a pregnant uterus of four-and-a-half months removed by mistake for a myomatous tumor; the small intestine completely cut in two in a mass of fibrous lymph; and a bloody fountain squirting from an ectopic pregnancy ruptured far out near the pelvic wall, then do you grow cautious in action and reticent in prognosis, although in a sense you are a stronger and safer surgeon because you know the imminent possibilities with which you may have to contend. Such was not the man in the western portion of our own State who opened the abdomen of one of his women patients, clipped off the ovaries and tubes without ligation as he would spay an animal, and closed the incision—with what result within a few hours it is not necessary to relate.

Now, how much abdominal surgery and gynecology should a general medical practitioner know? As much as he possibly can without detracting from

*The earlier announcement of Maragliano's work was made at Bordeaux in 1895.

†Read before the Bucks County, Pa., Medical Society, at Newtown, Pa., February 12, 1908.

the general medical information which it is incumbent upon him to acquire. The weekly perusal of a first-class medical journal will furnish hints at diagnosis and treatment which will well repay the time consumed in reading them. Then, in a case of desperate urgency with no assistance at hand, I will endorse the statement of the surgeon I have quoted and will say that under such circumstances, and only then, should each and every medical man be able to perform an abdominal section. Do not forget this, however, as the well-trained medical men that you all are—for permit me to say that I have learned to admire and respect the ingenuity and self-reliance of the average country doctor, and his ability to recognize in most cases the gravity of acute though obscure developments—do not forget, I repeat, that there are terrible conditions that may be encountered in the pelvic and abdominal cavities, a few of which I shall touch upon at this time.

Internal Hemorrhage.—Thus, in the first place, every medical man should know by heart the symptoms of internal hemorrhage, which may result from rupture of an ectopic gestation-sac, the bursting of a pus-tube or of a cystic ovarian growth, or which may follow a traumatism or strain resulting in some visceral rupture, as of the stomach, spleen, or bowel. I have seen a patient, a man, bleed to death from an unrecognized complete vertical rupture of the spleen induced by a blow from a wooden leg received in a fight with the one-legged man. I have seen a man die upon the operating table four days after an extensive rupture of the bowel caused by violent efforts to save himself from falling beneath a wagon which had almost run into him while riding upon his bicycle. Early intervention in both of these cases would probably have saved life. Only this last summer I was hastily summoned by telephone to a town fifteen miles from my city to see a woman dying from rupture of an ectopic gestation-sac six hours after her physician had suspected that such an accident had occurred. Would any one of you wait six hours under such circumstances as this before opening the abdomen yourself or summoning the aid of a surgeon? I do not think so. Yet in this instance rupture had taken place at six o'clock Saturday evening, the condition not recognized or suspected until four o'clock Sunday morning, when the pulse-rate was 150 or more and the patient was blanched and shocked almost to unconsciousness, and the surgeon not summoned for another six hours, when it was too late to attempt an operation. An acute paroxysm of pain, followed immediately or shortly by collapse, with a pulse-rate of 120 or over—thready and collapsible, extreme surface pallor with perspiration, and loss of consciousness, should be a well-known picture to every medical man meaning one thing only—internal hemorrhage. The treatment is the same whatever the source of the bleeding, whether mesentery, spleen, bowel, or broad ligament. The important thing to know is that the abdomen must be opened at once, either by yourself or with the aid of an experienced surgeon—but if the diagnosis of concealed hemorrhage is not made, how can the appropriate treatment be instituted in time?

Ectopic Pregnancy.—It is gratifying to note that the possibility of the occurrence of an ectopic pregnancy is being very generally recognized by the profession at large. In my student days at the University of Pennsylvania we, as a class, were taught that there was a curious but exceedingly rare obstetric accident known as extrauterine pregnancy, but that so infrequently did this occur that in all probability not one of us—and that a class of over 140 men—would ever see a case of the serious accident. We now know that ectopic pregnancy occurs about once in three hundred gestations, and that every man in active general practice will probably sooner or later encounter a case of the kind. In fact, gentlemen, the first abdominal section that I was called upon to perform was for rupture of a repeated extrauterine pregnancy, the first operation having been made by my friend and teacher, Dr. B. F. Baer, of Philadelphia, just two years before. One of the abdominal surgeons of my city has said that on an average he operates upon twenty-five ectopic pregnancies yearly, and not a season passes for any one of us without several cases of the kind being encountered either in our own work or in that which is referred to us.

Appendicitis.—Again, in these days when appendicitis is either more generally recognized and differentiated from other obscure abdominal conditions, or is, as I believe, actually increasing in frequency, it is most important that an early diagnosis of the condition be made. A suggestion in diagnosis which has recently been published by that practical surgeon of New York City, Dr. Robert T. Morris (*Jour. Amer. Med. Assoc.*, January 25, 1908), is well worth emphasizing. You all know the position of McBurney's point (an inch and a half from the anterior superior iliac spine on a line extending from the spine to the navel) and its value in diagnosing inflammation of the vermiform appendix. Morris now claims that this point is only of secondary importance and must give place in significance to another point situated an inch and a half from the opposite end of this spino-navel line—that is, at a corresponding distance from the navel and about six inches distant from McBurney's point. This we may term the point of the right lumbar ganglia of the sympathetic nervous system. Tenderness over this spot, according to Morris, is of considerable significance, as follows: If the point shows tenderness to any degree, even if pressure over McBurney's point elicits no tenderness, there will inevitably be found a chronic or subacute inflammatory condition of the vermiform appendix, provided that the corresponding point to the left of the navel (the point of the left lumbar ganglia) show no tenderness upon pressure. If both right and left lumbar ganglia are sensitive upon pressure, then the trouble lies in the pelvis, in the Fallopian tubes or ovaries, while absence of tenderness over either of these ganglia in the presence of obscure abdominal symptoms will indicate trouble above the region of the appendix. If this statement be true—and Dr. Morris speaks with considerable assurance, after a careful study of the condition—then we have here an excellent addition to our means of diagnosis of pelvic and abdominal pathology, and one which we all should thoroughly acquaint ourselves with.

Given a case of suspected or of clearly recognized appendicitis, how long should palliative measures be continued and when should surgical aid be called in? A safe rule to adopt is this: In cases that are not immediately operable, as indicated by the gravity of the symptoms, apply the ice bag and continue the use of purgatives for twelve or fifteen hours, but do not administer an opiate of any kind. If at the expiration of this time the symptoms have not ameliorated or have grown worse, further delay in instituting operative measures is dangerous. If, on the other hand, the temperature falls gradually, the pain grows less severe, and the general condition of the patient is improved, the nonsurgical measures may

be continued for another period of twelve hours, while a close watch is kept upon the course of the disease. Right here, however, it is incumbent to bear in mind a very important truth. In the cases of fulgurant appendicitis, with the early development of gangrene just at the time of the onset of the gangrenous change there will frequently occur a sudden and almost complete arrest of the symptoms. The temperature will fall to the normal and the paroxysms of pain will cease, and the unwary physician may be deceived into a fatal inaction. Three years ago, at 11 o'clock at night, I was called by long-distance 'phone from Uniontown, Pa., and asked to take the midnight train for Pittsburg in order to operate upon a case of appendicitis the following morning. When I saw the patient, a woman of thirty-two years of age, at 10 o'clock that morning every symptom had disappeared. There was even no abdominal rigidity. I was impressed, however, by the remarkable appearance of the woman's face. Her expression was one of most intense anxiety, and this, coupled with the history of an acute suppression of the symptoms, decided me to proceed with the operation. In this case not only was the appendix for one and a half inches the seat of gangrenous change, but for two inches around the mesentery was hard and green. Had I been deceived by the apparent improvement in the patient's condition death would have followed in from twenty-four to thirty-six hours. The moral is obvious: All cases of appendicitis require incessant watching, prompt action when operative measures must be resorted to, and a thorough knowledge on the part of the attending physician of the symptoms of gangrene and perforation.

The abdomen is a fascinating field of study to me, and I could indefinitely continue my remarks upon its interesting and frequently dangerous pathology and the need of a sharpening of our diagnostic and observational powers in regard to it. Time will not permit me to do this, however, and I hasten on to mention next some important conditions that are very frequently encountered within the adjoining cavity—the pelvis.

Uterine Curettage.—In December last I was asked to see, in consultation with a physician of West Philadelphia, a young woman who had given birth to a baby just two weeks before. The history of the case was as follows: The labor had been normal and the puerperium also up to the morning of the day upon which I was requested to see the woman. That morning the nurse called the attention of the attending physician to a purulent discharge which was coming from the vagina. A specular examination was made, when the discharge was discovered escaping from the cervical canal. Now, gentlemen, note that the convalescence had been normal in every respect and without the slightest elevation of temperature. A vaginal douche of bichloride solution or of some other antiseptic material would have answered every purpose in this case. The physician, however, determined to immediately curette and flush out the uterine cavity, which he did, as he told me, most energetically, using after the curettage a copious douche of creolin. One-half hour after the operation the patient suffered a sharp uterine hemorrhage and at the same time experienced a severe stabbing pain in the right chest, together with considerable dyspnea and a marked rise of temperature. The physician, who was hastily summoned, was unable to count the radial pulse, and I was sent for. I found the young woman conscious and quite alert to all that was going on around her. Indeed, as I leaned over her she whispered interrogatively, "Operation?" At her radial pulse only a thrill could be detected, but upon listening over the precordia I was able to count 98 beats to the half minute. Here was a patient with uterine hemorrhage, a temperature of 104½° F., a pulse rate of 200 beats per minute, a sense of oppression, with moderate dyspnea, no cyanosis, and a severe pain in the right chest—these symptoms all developing within half an hour after a curettement and intrauterine douche at the end of the second week of the puerperium. The diagnosis was plain. The condition was one of pulmonary embolism, due to dislodgment and escape into the general circulation of a small placental clot. Fortunate was it for the patient that the embolus was minute. Had it been a little larger death would probably have been almost instantaneous. As it was the clot had been swept into the pulmonary artery and thence had found lodgment in one of the end arteries of the lung, where it had doubtless given rise to a small infarction in the lung tissue. Under the careful use of strophanthus, quinine, absolute rest, and the ice cap, a complete recovery resulted in three days. My friend, Dr. Richard C. Norris, to whom I related this interesting occurrence, said he had met with a similar experience one year ago in the hands of another physician, that patient also recovering from the alarming condition. When I had quietly remonstrated with the physician because of his unnecessary invasion of the uterine cavity, he replied that he had thought it perfectly safe to curette the uterus at the end of the second week, as by that time he believed the organ had thoroughly involuted. He was greatly astonished when I told him that it required six weeks for involution to be accomplished under the most favorable circumstances.

The truth I would have impressed upon us all by this case is this: Even such an apparently simple procedure as intrauterine curettement is not unattended with danger, and the axiom, "look upon the uterine cavity and the bladder as forbidden territories," is one well worth propagating throughout the profession. At a meeting of the Obstetric Section of the American Medical Association at Saratoga a few years since it was stated by one of the distinguished surgeons that the operation of dilatation and curettement of the uterus as done by medical men at large was attended by a mortality of two per cent., and the surprising statement was endorsed by other eminent abdominal surgeons. This mortality results from septic infection, perforation of the uterine wall, and rupture of the cervix and lower uterine segment with hemorrhage from the circular artery of the cervix. In my own interesting case a fatal termination almost resulted from pulmonary embolism, the clot coming from the placental site. In my own work rarely do I find it necessary to enter the uterine cavity after labor, and in the few cases in which this procedure is indicated, the finger, placental forceps, or the dull curette carefully manipulated will answer every purpose. Especially is it incumbent upon us to remember that at least six weeks must elapse before a puerperal uterus returns to its normal size, and that during this period puerperal sepsis, uterine hemorrhage, embolism, and posterior displacement of the heavy organ may follow indiscretions on the part of the patient or of her attending physician.

Posterior Displacements of the Uterus.—Next, let me urge upon you all the great importance of recognizing displacements of the uterus at as early a period as possible, together with the need of an immediate correction of the malposition. Here is

a phase of gynecology with which every medical man in the country without exception should be acquainted. I have frequently been astounded at the statements made to me by physicians in general practice that they never make vaginal examinations. Thousands of women throughout the country suffering from varying degrees of retrodisplacement of the uterus are treated by prescriptions and plasters for backaches, headaches, and nervousness, when a half minute's work would correct the primary cause of the symptoms and bring incalculable relief to the sufferers. Why this general antipathy to vaginal exploration should exist I cannot imagine. This I do know, however. This neglect on the part of the physicians has been responsible in many instances for the turning of worthy patients over into the hands of the Christian Scientists and osteopaths, who by their suggestion and deep massage have afforded a temporary relief from the sufferings, but necessarily not a cure of the organic condition. Believe me, it is as impossible to diagnose uterine and pelvic trouble without such examinations as it would be to recognize lung changes by percussion over a thoroughly clad chest. The index finger of every physician should be trained to detect the position and size of the uterus as well as any gross pathological change in the surrounding pelvic viscera, such as tumorous formations and ovarian displacements. In other words, it is necessary to recognize the site of the trouble. Then, if you feel that other experience than yours is needed, call in the necessary aid for consultation and advice. The inability to make a thorough diagnosis of pelvic disease in any given case should not be a cause of mortification to any conscientious man, for even the frequent making of vaginal examinations does not mean the making of a correct diagnosis in every case. Thus, a few years ago a woman physician in my own city, whose practice was then extensive, but who has now departed to her final rest, treated in her office a poor woman twice weekly from October until March for retrodisplacement of the uterus, for the correction of which condition she had introduced a Smith-Hodge pessary. At each visit the doctor assured the woman that she was much improved, but as the symptoms persisted and the suffering even grew more severe, the woman, in March, came to my clinic for relief, claiming that she was no longer able to pay the price of the office visit. On examining her I found an acutely anteflexed uterus, behind which lay a greatly enlarged, prolapsed, and adherent right ovary, which I ultimately removed. This body had been mistaken by the physician for the retrodisplaced fundus of the uterus. Here was an egregious error for which it is difficult to find an excuse; but let me assure you that we all are subject to errors in diagnosis—even the best of medical men—and this, as brethren, we may condone. What is incomprehensible to me, however, in the case I have quoted was the assurance of steady improvement which was given the poor woman at each visit when under the circumstances this improvement did not nor could not be.

It is remarkable how quickly relief will be afforded by restoring a displaced uterus to its normal position. Headaches, depression, and backaches frequently disappear as if by magic, and patients have returned to my office within five minutes of their departure to tell me they have not felt so well for years. Every gynecologist will bear similar testimony. The explanation for this relief is to be found in the removal of pressure from the network of sympathetic nerve plexuses which is lodged in the sacral hollow, and in the removal of the obstruction to the pelvic circulation, which must invariably result from a twisting, however slight, of the broad ligaments.

Cancer of the Uterus.—Finally, permit me to conclude this address with a few words upon that *bête noir* of medical men, cancer of the uterus. There is prevalent throughout the profession as well as among the laity a very common and a very serious misconception of facts concerning the menopause. Let me say at the outstart that the menopause is never normally accompanied by flooding. Either is the menstrual life abruptly ended for good—which is unusual; or the woman experiences a steady and gradual diminution in the quantity of the menstrual flow until it is finally suppressed—which is more common; or she passes through the well-known "dodging period," missing the flow one month to have it return the next month in its usual form, and repeating this process for six months or a year until the flow permanently disappears—which is most common. If at the age when the change of life should be expected there is experienced a sudden and unusual discharge of blood, a pathological condition exists. Trouble is to be anticipated, and in the vast majority of cases this will take the form of a malignant change in the cervix or more rarely in the fundus of the uterus. A vaginal and specular examination now becomes imperative, and occasionally an intrauterine curettement, and any delay, even for a week, on the part of the woman's medical adviser becomes reprehensible. Thousands of lives have been lost and terrible suffering inflicted upon the unfortunate women through the adoption of the temporizing plan. When these poor creatures do come upon the examining table it is often found that it is too late to do anything in the radical line of treatment. The vaginal wall, bladder, and broad ligaments have become invaded by the cancerous change and total extirpation of the growth is impossible. I would that every practitioner of medicine could have this truth indelibly branded upon his memory. Hardly in any other pathological condition to which the body is heir is the need for early intervention so urgent. Flooding at the menopause, then let me repeat, and return of the bloody discharge after it has once been arrested for a year or two, almost invariably spell malignancy.

In this paper I have merely touched upon topics on each of which papers, and even volumes, could readily be written. If in so doing I have been permitted to plant some new impression that may bear good fruit, or even if I have brushed up some forgotten point or awakened some latent memory, my work will not have been in vain. How much gynecology and abdominal surgery should each medical man know? Just enough to save life and to afford to those who come to them for relief the best possible chance for the recovery of the health which is so dear to each of us.

1623 Walnut Street.

Acute Pemphigus of Childhood, with Especial Regard to Etiology.—A. Longo gives an account of his experiments to determine the etiological factor in the production of acute pemphigus in children. It is generally admitted that the disease is contagious, and in the majority of cases in which the exudation from the bullæ has been examined *Staphylococcus aureus* has been found. The occurrence in children so much more frequently than in adults seems to be due to the greater vulnerability of their skins. The author examined the fluid obtained from the bullæ of four children observed by him. In all of them he found a pure culture of *Staphylococcus aureus*. The author concludes that the presence of staphylococci in the bullæ is not accidental, but has to do with the cause of the disease.—*Rivisti di Clinica Pediatrica.*

THE DIAGNOSIS AND TREATMENT OF THE MORE COMMON DISEASES OF THE SKIN.*

By EDMUND LINDLEY COCKS, M.D.,

NEW YORK.

DERMATOLOGIST TO THE HARLEM HOSPITAL DISPENSARY, ETC

In selecting the title of this paper our worthy president had in mind that Dermatology is the youngest of the specialties, that its classification is not perfect, and that the diagnosis of cutaneous lesions previous to 1896 was confusion confounded. The writer was present at the International Dermatological Congress held in London in September, 1896, to which cases were sent by visiting dermatologists from all parts of the civilized world. Forty per cent. of these cases were found to be the same disease classified differently by Germans, English, Americans, and French. In Berlin three years ago, and in our country the past summer, a large number of clinical cases were shown, which no doubt will result in still further clarifying dermatological nomenclature.

I should like to continue along this line of thought a little further, but as our president has restricted my paper to a discussion of the cutaneous cases seen in consultation that should have been diagnosed by the general practitioner, I must forbear.

In dispensary practice I find that the cutaneous manifestations of scabies, pediculosis corporis, and pediculosis pubis are readily recognized. In private practice, however, I know of no other group of cases that is so often wrongly diagnosed.

In scabies, the multiform lesions resulting from scratching may disguise the real trouble. For that reason there is hardly a skin affection that may not appear to be present. The following points always present in a case of scabies will, if memorized, aid greatly. Examine carefully between the fingers for the burrows, also about the wrists. Note especially the nipples in the female, and, in the male, the penis. In babies the papulopustular eruption of the heels and the soles of the feet is typical. For class or office demonstration the Acarus can be obtained by introducing the point of a fountain pen into one of the burrows; the ink will follow in the wake of the parasite, and if a needle be pushed to the bottom of the canal and then slowly withdrawn, the Acarus may be found on its point.

The pediculi corporis feed on the body, simply utilizing the clothing for a lodging place. The long scratch marks on the shoulders, loins, and buttocks, the numerous denudations with a central small blood clot, the charactertistic pin point blue spots, "maculæ ceruleæ," due to the minute hemorrhages as a result of the bite, the finding of the pediculi in the clothing, all point to but one diagnosis.

The pediculis pubis, or crab louse, attaches itself to the hairy portion of the trunk, especially in the pubic or axillary regions. A careful examination will reveal its presence, and that of the nits.

Cases of erythema annulare, "a sub-division of erythema multiforme," pityriasis maculata et circinata, and a circinate syphilide have frequently been referred to me, diagnosed as tinea circinata or ringworm of the body; the physician stating that the case puzzled him on account of its stubbornness in responding to the treatment usually recommended for the ringworm.

Erythema annulare is generally preceded by constitutional symptoms, pain in the head, back, and limbs; the temperature is 100° to 104°, and a history of gastric disturbance is usually elicited. Most, if not all, of the acute symptoms have disappeared before the case comes under the observation of the dermatologist. Erythema annulare presents typical rings, from a dime to a dollar in size, with a clear erythematous center. The border is raised, perceptible to the touch and eye, and is not scaly. The patients complain more of a burning than of an itching sensation.

A ringworm commences as a papule, soon becomes scaly, enlarging at the periphery, clearing up in the center, the rings never coalescing or even touching. Pruritus, although not marked, is present. The patient never complains of a burning sensation. It is at this stage that the diagnosis is made, and that tincture of iodine, formaline, or other drug, is applied, setting up a dermatitis, so disguising the original lesions that the consultant is momentarily at sea. In erythema annulare, pityriasis maculata et circinata, and the majority of cutaneous diseases, new lesions which will aid us in our diagnosis are always found if carefully looked for.

A circinate syphilide, the third of the ring group, is made up of individual papules arranged in semicircles or complete rings. The rings *may touch* and *may overlap;* there is a well defined induration and a slight redness between the papules which completes the ring. The neck and face are the favorite site for tinea circinata and a circinate syphilide.

The rings of tinea circinata are never broken, they do not overlap, and are always scaly and itchy. The reverse is true of the syphilide, in which the rings may be broken, they do coalesce, and there is an absence of scales and pruritus.

Tinea tonsurans, or ringworm of the scalp, alopecia areata, and alopecia syphilitica make up a group of scalp affections that deserve more time than is at my disposal. The lesions of ringworm and alopecia areata are generally circular. The ringworm presents broken hairs or stubs, and the base is more or less scaly, depending on the presence of the small or large spores.

On epilation, the root of the ringworm hair is always seen to be swollen. Itching is a prominent symptom, and the onset is gradual. The reverse of the picture is true of alopecia areata. The floor is pearly white, there is entire absence of scales and pruritus. A history of neuralgic pain, preceding the appearance of the bald spot by several days, may be elicited. The shaft of the hair is not affected, but the root is found to be atrophied instead of swollen.

The moth-eaten appearance of the scalp showing the lesions of alopecia syphilitica is so typical that to mistake it for ringworm or alopecia areata would be almost unpardonable—and yet this error is of frequent occurrence. If the picture of a hen-pecked husband, or as the scalp would look after an hour's seance with an angry hen, is kept in the mind, and compared with the round, scaly, and broken stubby hair, itchy lesions of ringworm, or the smooth, circular, non-itching one of alopecia areata, the mistaking of one for the other will be less frequent. It goes without saying that the prognosis and treatment depend on the diagnosis.

Impetigo contagiosa, pemphigus neonatorum, and a pustular syphilide are three of the skin diseases of early childhood that are not so clearly defined in the minds of general practitioners as I should wish.

The acute lesions of impetigo contagiosa are always discrete. The base is slightly erythematous, the contents of the vesicle are clear, but soon be-

*Read before the Harlem Medical Association, November, 1907.

come purulent. If the vesicle is not ruptured it dries up in a few days leaving a green scab, which soon falls off, leaving a red base. The favorite sites are around the mouth, chin, nostrils, and occiput; as there is more or less pruritus, the pus organism may be implanted by scratching on any part of the cutaneous surface.

Pemphigus neonatorum and a pustular syphilide are often diagnosed impetigo contagiosa. I saw two syphilitic patients in which this diagnosis was made too late to avoid a fatal termination. Pemphigus neonatorum is not always a syphilitic manifestation, as some dermatologists believe. The eruption appears about the second or third week of life, generally on the palms of the hands and the soles of the feet, also about the thighs and buttocks. The lesion is a bulla, not a vesicle as in impetigo contagiosa. There are very slight if any areolæ.

Pemphigus syphiliticus may also appear during the first week of life. The contents of the bullæ are always pustular. It attacks the fingers in preference to the palm. The classical figure of infantile syphilis is often present, and if recognized makes an error in diagnosis impossible.

Eczema pustulosum, the last of the pustular group to be differentiated from impetigo contagiosa, is a dermatosis in which the entire thickness of the skin is involved, and not the epidermis only. The pustular is the third stage of eczema, being preceded by an erythema. The formation of vesicles and oozing of infected serum cause pustulation. Impetigo is pustular almost from the first.

Eczema infantile, intertrigo, and dermatitis seborrhœica are found more often in infancy than all other cutaneous diseases. According to Crocker's statistics they form about 60 per cent. of all cases. The necessity of a correct diagnosis is obvious, and if our treatment is successful, two-thirds of the dermatological cases that are brought to us will be relieved, greatly to our honor and satisfaction, and to the relief of patients and friends.

The lesions of infantile eczema do not differ from the acute eczema of the adult. Erythema papules and vesicles are always present, the escaping serum from the ruptured vesicles forming crusts familiar to all.

An intertrigo is generally superficial and is due to local irritation by acid urine or feces, or confined perspiration in fat children. The erythema is always deeper in the folds, gradually disappearing towards the periphery. The exudation is thin and does not stiffen linen, differing in this respect from that of an eczema. An eczema may develop in an intertrigo, and it then assumes all the characteristics of a true eczema.

A congenital syphilide of the buttocks may be mistaken for an intetrigo. An intertrigo is generally limited to the site of the napkin. The erythema of a congenital syphilide may extend down the legs even to the soles of the feet.

Eczema seborrhœicum, especially of the buttocks, is seldom, if ever, moist, and only slightly itchy, differing in these two points from eczema. The erythema is more pronounced at the periphery than at the folds, the advancing border resembling that of a ringworm, it being raised and scaly. To repeat: In eczema the discharge stiffens linen, the discharge of an intertrigo does not. The erythema of intertrigo is deeper in the folds, fading towards the periphery; the reverse is true of eczema seborrhœicum. If the recognized treatment for one is applied to the others, great tribulation and not cure is the result.

Tinea barbæ or sycosis parasitica, sycosis non-parasitica, and eczema of the beard are often mistaken one for the other. The primary lesion of tinea barbæ is always scaly. It soon becomes indurated, and the lumpy or boggy condition so typical of ringworm soon appears. In sycosis non-parasitica the hair stands in the center of a small lake of pus. The hair is easily extracted, and without pain, while epilation in ringworm is always painful. Eczema pustulosum of the beard is always a secondary infection. The ever present primary lesions of eczema, vesicles, papules, and weeping are to be found here as elsewhere. In eczema and sycosis the sensation is a burning one, while in tinea the patient complains of a severe pruritus. In tinea barbæ the lesions are lumpy, scaly, and itchy. In sycosis and eczema, they are pustular, not scaly, and may be covered with crusts.

Tinea versicolor, chloasma, and leucoderma are often confounded. Tinea versicolor, or the so-called liver spots, is due to the presence of the vegetable parasite *Microsporon furfur*. It appears as yellowish brown spots, irregular in shape, which may spread over the entire body. They are found chiefly on the trunk, although the neck and flexor surfaces may be affected. The pruritus is moderate. If the disease is not treated it may last an entire lifetime. If tincture of iodine is applied to the tinea it stains the spores a mahogany brown.

Chloasma is due to an increase of the normal pigment. It may be found along the forehead, cheeks, angle of the eyelids, upper lip, and cheek, and is of a dark brown color. There are no subjective symptoms.

In leucoderma there is an entire absence of pigment. It appears as one or more white spots on a level with the surrounding skin. There is no scaling. The spots, which are sharply outlined, are surrounded by an abnormally dark pigment, which gradually fades into the healthy skin.

In closing the subject of diagnosis, kindly pardon one suggestion: The microscope is of great aid in the study of skin diseases; by its assistance in the majority of the cases that I have presented this evening for your consideration the differential diagnosis could have been made.

Treatment.—Babies and adults affected with scabies or pediculosis should be bathed in warm water, to which borax and tincture of green soap have been added, and allowed to soak for half an hour. After drying, a two per cent. unguentum hydrargyri ammoniati applied night and morning for a week is all that is necessary to effect a cure.

Babies and children should have an ointment of balsam of Peru, ʒii; precipitated sulphur, ʒi; rosewater ointment, ℥ii, applied twice a day. For adults an ointment composed of naphthol, gr. lxxx; green soap, ʒvi; rosewater ointment, ℥ii. ʒii to be thoroughly rubbed into the skin twice a day, will result in the death of the parasite in one week. The patient is then to take a second bath, put on clean underclothing, and report. Two teaspoonfuls of precipitated sulphur sprinkled between the bed sheets is a useful adjuvant.

The subjective symptoms of erythema annulare respond quite quickly to

℞
Sodii salicylatis ʒv.
Misturæ rhei et sodæ, ℥iii.

M. Sig.: A teaspoonful in a wine-glass of water every three hours. A lotion of pulveris calaminæ precipitatæ; zinci oxidi, aa ʒii; acidi phenici, ♏xxx;

aquæ rosæ ℥iv, will relieve the objective symptoms.

A circinate syphilide commences to resolve after a few hypodermic injections of salicylate of mercury, gr. i. One or two gentle applications of formaline to the ringworm of the body is all that is necessary for a perfect cure.

The cure of tinea tonsurans demands long and persistent treatment. The patient should wear a muslin nightcap and be isolated. The hair is to be clipped, thirty or more hairs to be epilated daily, and the following ointment rubbed in with a stencil brush twice a day:

℞

Ung. hydrarg. ox. rub. ℥iss
Ung. sulphuris, ℥iii
Ung. aquæ rosæ, ℥i

Our alopecia areata patients should be treated systematically, and an application of pure phenic acid made every two or three weeks. As soon as the new growth of hair appears a daily massage with 30 grains of salicylic acid in one ounce of olive oil will complete the cure.

The physician should remove the crust or open the moist lesions of impetigo contagiosa himself and apply to the base of each lesion peroxide of hydrogen to be followed by an ointment consisting of Ung. hydrargyri ammoniati 5 per cent., or ichthyol same strength, in Ung. zinci oxidi. This is to be rubbed in twice a day until the patient is cured, the nurse being instructed in the modus operandi. Bandaging the parts will aid greatly.

The pustular syphilide responds very kindly to lotio nigra externally and tablets of mercury and chalk internally. Of vital importance is the care of the baby's nutrition.

Pemphigus neonatorum non-syphiliticus requires the same careful watching as the luetic form. The calamine and zinc lotion applied every three or four hours is very acceptable.

As an intertrigo is generally due to acid urine, feces, or confined perspiration, by removing the cause, separating the contiguous parts, and the application of ℞ Magnesiæ carb., ℥ii; zinci oxidi, ℥ii; aquæ rosæ, ℥iv, our patient is relieved.

An application of one dram of resorcin in three ounces of water, or of rosewater ointment to the advancing border of dermatitis seborrhœica will check it.

Epilation is our sheet anchor in tinea barbæ. This should be done by the physician, the parts being thoroughly cleansed with hydrogen dioxide, and the ointment recommended for tinea tonsurans applied. The patient is to apply the same night and morning. After the hairs of sycosis non-parasitica have been removed, an ointment of ichthyol 30 per cent. in rosewater ointment has given satisfaction.

Eczema of the beard yields very slowly to treatment. The application depends on the stage of the disease. A chronic eczema requires a stimulating ointment, as oil of cade, one dram to the ounce of zinc oxide ointment; or, if moist, diachylon ointment; if inflamed the more soothing lotion of calamine and zinc is to be preferred.

Leucoderma we can do very little for, except to stain it with walnut juice to correspond in color with the surrounding skin.

It has been the writer's experience that the more one treats a case of chloasma, the larger the lesion grows. If it is due to internal or constitutional troubles, these conditions of course should be treated.

Tinea versicolor responds quickly to the application of green soap allowed to remain in contact an hour or more, then washed off, and a solution of hyposulphite of sodium, ℥i, in rosewater, ℥iv, thoroughly applied daily. If any part is overlooked, a reappearance is sure to follow.

156 West One Hundred and Nineteenth Street.

A RATIONAL METHOD OF TREATMENT IN CHRONIC ENDOMETRITIS.*

By JOSEPH M. RECTOR, M.D.,

JERSEY CITY, N. J.

CONSULTING SURGEON TO NORTH HUDSON HOSPITAL; ATTENDING GYNECOLOGIST TO JERSEY CITY HOSPITAL; ASSOCIATE IN GYNECOLOGY, NEW YORK SCHOOL OF CLINICAL MEDICINE, CHIEF OF CLINIC, GYNECOLOGY, WEST SIDE GERMAN DISPENSARY, NEW YORK CITY.

An advancement in the treatment of this disease should be a sufficient apology for calling attention to a generally neglected subject. Little thought has been recently spent upon it by the profession at large and few general practitioners or postgraduate students have any degree of practical knowledge concerning its exact condition, or its possible mode of relief. It has seemed wise to me that I should fully explain this method of treatment, in the hope that your time spent here tonight may prove of manifold advantage in your routine gynecological work. There is no disease peculiar to the female in which neglected or improper therapeusis will do so much harm to the patient or cause so much dissatisfaction to the physician.

Taking as a basis for my work a paper writen by Dr. A. H. Goelet, and read before the Gynecological Section of the American Medical Association in 1899, I have perfected the treatment which I shall here describe. The main objective symptom to which your attention is called and for which relief is sought, is "symptomatic leucorrhea." The presence of a discharge at the vulva, within the vagina, or at the external os uteri, will necessitate the determination, first, of its exact location, and, second, of its positive cause.

The mucous membrane of the body of the uterus is but one to two millimeters thick, resting smoothly upon the musculature of the organ, without any creases, folds, or projections. Many tubular glands with a single canal, spirally placed, and having a funnel-shaped orifice, open directly upon the surface. The interglandular structure is composed of connective tissue fibers, with many round, flat, star, and spindle-shaped cells. The secretion is normally alkaline and only sufficient in amount to keep the cavity moist. The epithelium is cylindrical and ciliated.

The mucous membrane of the cervix differs somewhat; it is thicker and more sharply divided from the muscular layer. Upon the anterior and posterior wall the membrane is thrown into transverse folds, after the manner of the ribs of a leaf and is often called the "palmæ plicatæ." The glands (glands of Naboth) are tubular with single canals, but having many lateral processes or projections with mouths opening into the valleys of the transverse folds. The mucous secretion is normally alkaline, of a thick, tenacious character, filling the canal and often projecting from the os externum. The round cells are fewer in number. Long and slender spindle-shaped cells are present. The epithelium is cylindrical and ciliated.

Continued passive congestion and infective disease are responsible for the pathological changes in the corporeal and cervical mucosa; with the one

*Read before the North Hudson County Medical Society.

follows the disturbance of correlation between vascular supply, innervation, and mutual relationship with other structures: with the other follows congestion and inflammation, plus the peculiar characteristics of the individual disease.

Simple catarrhal or congestive endometritis or hyperemia of the endometrium, results in a hypersecretion with a thin, watery, odorless, and non-irritating discharge. As the cervical mucosa becomes involved and its secretions are intermingled, we find the milky, albuminous leucorrheal discharge of a thick, ropy, and viscid consistency, mucoid at the cervix and opaque when passing into the vagina. With the correction of the congesting cause these symptoms disappear and the parts will return to their normal condition, provided this functional derangement has not resulted in pathological changes.

Long continued irritation and congestion bring about the changes found in the chronic form of this disease, to wit: primary infiltration and proliferation: secondary hyperplasia of muscle, glands, and connective tissue. Congestive endometritis and constitutional endometritis, subacute or chronic, are the familiar types of this disease. Proper care and adequate treatment must be instituted before the pathological process entirely obliterates the normal state. Here, as in other portions of the body, nature's trend is toward recovery, and our duty ceases when we have relieved the exciting cause and applied the proper treatment.

With the advent of infective disease, the leucorrheal discharge becomes creamy or yellowish, greenish or brown, or mixed with small quantities of blood: mucopurulent or purulent, odorless and non-irritating, or profoundly offensive and scalding: itself alkaline in reaction, but acid when intermixed with the acid products of inflammation and the decomposing secretions of the vagina. The amount varies from continuous moisture to a constant excessive discharge, requiring the continual use and constant change of the toilet napkin.

The first principles of modern therapeusis, as applied to diseased conditions affecting mucous surfaces, may be described as (*a*) frequent cleansing of the surface with a non-astringent, non-irritating solution, for the purpose of removing the adhering secretion; (*b*) opening the mouths of the glands, thus relieving any retained secretions and prevent germ propagation; (*c*) stimulating glandular activity directly, or indirectly through the secretory nerves; (*d*) replacing the normal equipoise between vascular supply, innervation and mutual relationship.

This is the exact purpose of the treatment I am about to describe and I have accomplished the same by means of the galvanic current, using the negative pole within the cavity of the uterus, and a simultaneous irrigation of a non-astringent, non-irritating solution.

Massey described the general action of the galvanic current as having the power of direct cellular stimulation to muscular tissue, glandular and secretory organs, independently of the innervating or trophic nerves, and this general tissue stimulation influences nutritive repair, lymphatic activity, and tissue metabolism. The negative pole has the power to dilate canals and increase moisture and drainage. Thus by interuterine negative galvanism, dilatation, irrigation, and drainage, I have fulfilled the requirements.

With the patient in the dorsal position and the dispersing (positive) electrode upon the abdomen, a speculum is placed in the vagina, with its blades generously separated. This brings into view the cervix and the adjacent parts. The active (negative) electrode is introduced into the uterus and a constant current of five to fifteen milliamperes turned on. Stronger currents are not to be used, for fear of the soft liquefaction and stricture which may follow its caustic action. The surrounding muscular tissue softens, by reason of abstraction of water from the tissues, bubbles of hydrogen gas will be seen issuing from the os uteri, and a copious watery or mucoid discharge flows readily from about the now loosened electrode.

After an application of five to ten minutes the sounds are removed and the irrigator, which is also an electrode, is inserted in their place. While the current is still passing the cleansing solution is allowed to flow. Upon withdrawal of the irrigator, the canal will be found softened, patulous, and free from discharge. The dilatation will remain a sufficient length of time to allow any additional application to be made to the cavity of either uterus or cervix and without any muscular interference.

To begin with, your source of supply and class of current must be perfect and absolutely under your control, positively free from any interruptions of current, sudden stoppage, or increased milliamperage. The milliampere meter must register accurately the amount and constancy of the current passing. The wires, binding posts, and electrodes must be properly insulated. The current must not be turned on until the electrode is in position, and must then be raised slowly to the required strength. The current must be slowly reduced before the electrode is removed. These precautions are advised because of the adverse mental effect that any disturbance will have upon the apprehensive patient. If the woman suffers any considerable amount of pain, burning sensation, or sudden electric shock, she will become frightfully nervous and insist upon ending the treatment.

It is well nigh impossible to obtain good work from a current generated by a collection of cells, because of the constantly changing cell power, by reason of improper care and the general ignorance of the ordinary physician regarding their management. Every community now has electric power for commercial use, and the company furnishing the same will willingly count you among its patrons. If the current supplied is a constant one (direct current) it can be carried directly to your cabinet, which must be wired to a corresponding voltage. If the current is an interrupted one (indirect current) it must first be used to operate a motor. The motor is connected with a dynamo from which will be generated the necessary direct or galvanic current to operate the office cabinet.

In beginning the dilatation, the size of the uterine electrode is selected which will readily pass into the canal without giving any pain: in the same gentle manner and with the same aseptic precautions as you would pass a uterine sound for diagnostic purposes. The electrode, which is best made of copper, and properly insulated, is passed onward until the collar which marks the beginning of the insulation, presses against the external os. The length of the exposed electrode is shorter than the canal, as I have found that when the tip of the electrode rests against the fundus of the uterus, the patient often experiences a disagreeable (temporary) attack of painful uterine contractions.

As the canal gradually dilates and softens, electrodes of increasing size are used, until the entire canal is sufficiently dilated to admit freely the irrigating electrode. As soon as the irrigator is in proper position and the desired current is passing,

the cleansing fluid is allowed to flow and freely wash the entire mucous surface. Thus we have the concurrent action of the passing current and the irrigating solution. It is well gently to move and rotate the irrigator during its use, as it facilitates the cleansing by bringing every part of the mucous surface under the action of the solution.

I have found one-half to one per cent. solution of the tincture of iodine to act best as the cleansing agent.

The dispersing electrode, 6 x 8 in., is made of copper, covered on its under side with felt and its upper side with rubber. Before making the contact, it should be well moistened with warm water and freely soaped.

The vaginal electrodes are made of copper, 11 inches long, have the usual pelvic curve, and vary in diameter from that which will penetrate the "pinhole os," to one which will give free dilatation. The entire length is insulated by being covered with vulcanized rubber to within two inches of the tip, in the smaller sounds, and two and one-half inches in the larger sounds. These larger instruments are used in the large subinvoluted uteri. An opening in the copper at the insulated extremity acts as the binding post.

The irrigator is 12 inches long, has a central hollow tube, ¼ inch internal diameter at the distal end, and 1-16 inch internal diameter at the uterine end. It has the usual pelvic curve. Beginning 2 inches from the uterine end, the tube is fenestrated on all sides. The fenestræ about the sides are larger than at the end. Around and about this irrigating tube are 4 small wires, which act as bridges and prevent the mucous surface from closing around the tube. They begin 4 inches from the uterine end and pass over it to be brought together ¼ inch beyond its extremity. The wires are raised from the tube along this entire length. The external diameter of the irrigator at the distal end is ⅝ inch and at the uterine end is ⅛ inch. The binding post is 1½ inch from the distal end. The irrigator is insulated by being covered with vulcanized rubber to within 4 inches of the uterine end.

Preferably a trivalve speculum is used, as the sides of the vagina are thus best kept apart. Beneath the handle a triangular pus basin is placed, which will catch all the return irrigating fluid or discharge, thus preventing the patient's clothing from becoming soiled.

In most instances, each application continues about ten minutes and is used every day or every other day, depending upon each individual case. The entire length of time under treatment will depend upon the progress made.

In the purulent forms of chronic endometritis, when the hyperplasia or hypertrophy has resulted in outgrowths or projections from the surface of the mucosa; or, when fungoid, polypoid, or hemorrhagic endometritis is present, the preliminary use of the curette is indicated.

EXAMPLES OF CHRONIC PRODUCTIVE INFLAMMATIONS IN EARLY LIFE.

By ROLFE FLOYD, M.D.,

NEW YORK.

THE chronic productive inflammations occurring so frequently in late middle life and old age are regarded by many observers as senile changes or replacement fibroses. Others, however, look upon this large group of connective-tissue changes as true inflammatory processes, due, like other inflammatory changes, to some irritant cause.

One argument in favor of the latter view, and one which seems very convincing to me, is the occasional occurrence of these changes in early life, before there is any senility, and before it is reasonable to suppose that the wear and tear of existence could wear out the parenchyma cells of the organs, and so prepare the way for the process of replacement fibrosis.

Another argument in favor of the inflammatory view is the fact that these changes seem, in some cases, to be due to the poisons of syphilis, of gout, or of alcohol.

I have three early examples of these chronic productive inflammations to report, two in the second decade, with no evident etiological factor, and one in the third decade preceded by three years of hard drinking.

CASE I. *Pulmonary emphysema, accompanied by hemoptysis, the symptoms beginning at the thirteenth year.*—Male, Russian, tailor by trade, 16 years old. Came to the Vanderbilt Clinic November 1, 1904. Three years before he began to spit blood on and off, to have a cough, to raise a little phlegm, and to have dyspnea on exertion. One year ago he had a few night sweats which did not recur. For five months he has been worse and has spit blood nearly every week. He has not lost flesh though he feels weak. He says he has had no fever. He has some headache at times. His appetite has been good and he has kept at work throughout.

Examination.—His general nutrition is fairly good. The percussion note is high pitched and of vesiculo tympanitic quality all over both chests. The breathing is of altered vesicular quality and obscured by sonorous and sibilant râles. A few fine râles are heard low in the right axilla. Neither I nor the Board of Health could find any tubercle bacilli in his sputum. He spat blood in my presence; it was bright and evenly mixed with mucus.

This patient was under observation at the clinic for 14 months. As his bronchitis and asthma improved somewhat under treatment, the sonorous and sibilant sounds diminished and the characteristic breathing of emphysema with its altered quality and prolonged expiration all over both chests became very distinct. No other changes occurred in the physical signs. There was always some bronchitis. There was never any localization of signs.

He spat blood at intervals through the entire period of observation, seldom going a month without this symptom.

He gained in flesh and strength in the spring of 1905, on the syrup of iodide of iron. He never lost any appreciable amount of weight, he never had fever, chills, or sweats and his general health remained fair. He did not stop working. Subsequent examinations of the sputum failed to reveal tubercle bacilli. January, 1906, I found him in substantially the same condition as when he first came under observation. After this he was lost sight of.

It should be stated that pulmonary emphysema is here regarded as a chronic productive inflammation of the lung, because, whether the lungs are enlarged or diminished in size, whether the air spaces are dilated or obliterated, the one essential pathological change in all cases of primary pulmonary emphysema is a proliferation of the connective tissue framework of the lung parenchyma.*

The above case, then, is an example of a chronic productive inflammation of the lungs occurring in early life and causing definite and gradually increasing symptoms.

*See Delafield's recently published "Lectures on the Practice of Medicine," Part II., page 396.

Case II. *Arteritis, discovered accidentally in a boy sixteen years old.*—Male, American, clerk by occupation; came to Bellevue O. P. D. on December 13, 1907, complaining of a dry cough of 3 or 4 weeks' duration. His father and mother are both living and well. He has three brothers and one sister, all well. Two children died in infancy, one from "pneumonia." His own health has always been good.

Examination.—Well nourished and well built; weighs 150 lbs. No evidences of hereditary syphilis. The mucous membrane of the throat is considerably thickened and somewhat congested. The lungs are normal. The heart is of normal size. Its action is good, regular, but rapid (from excitement); the sounds are normal, and there are no murmurs.

Both radial arteries are distinctly thickened, the left a little more than the right. There is no increased tension. The pulse corresponds to the heart action. The right temporal artery can be easily felt, while the left is scarcely palpable.

The urine has a specific gravity of 1.022. There is no albumin and no sugar. There are 10 grs. of urea to the ounce. After centrifuging, two or three hyaline casts were found.

This is an example of a chronic productive inflammation of the arteries occurring in early life and, as often, causing no symptoms whatever.

Case III. *Cirrhosis of the liver, with fatal hemorrhage at the twenty-fifth year of age.*—Male, American, butcher by trade, 25 years old; entered Roosevelt Hospital January 2, 1900. Three and one-half years ago he began to drink hard and did not stop until 6 months ago. Never had syphilis or rheumatism. Has always been well except for an attack of jaundice 12 years ago, which lasted 4 weeks and was not severe. Two years ago he began to suffer from morning vomiting and retching, which continued till he stopped drinking. One year ago he vomited about 2 quarts of dark blood in 24 hours and passed a considerable amount from the rectum. No pain was associated with this attack, but he felt pretty weak from it.

The same symptoms recurred one month later, but this time he only vomited about one pint of blood.

For the last 6 months, since he stopped drinking, he has felt well, his appetite has been good, and his bowels regular.

He never had a chronic cough, never had swelling of the legs or abdomen, no cardiac or renal symptoms, no bilious attacks. Occasionally has headaches, and lately often has nose bleeds.

At midnight last night he vomited 8 ounces of blood. He felt sick this morning but went to work, and vomited three more times—about 32 ounces in all. He has very little nausea and no pain, but slight abdominal discomfort. The blood he vomited was dark at first but bright the last time. His bowels have not moved since yesterday. He felt very weak after losing the blood, but feels stronger now that he is in bed.

Examination.—Color and nutrition good, tongue clean, some blood on the lips. Pulse regular and of good force—artery very slightly thickened, not contracted. Abdomen normal, no local tenderness. Extremities normal. Temperature 99° F. Pulse 118. Respiration 24. Urine specific gravity, 1.032, no albumin, a considerable number of pus cells.

He was given two rectal saline injections of one pint each. He was comfortable through the afternoon, but began to bleed from the mouth and rectum in the evening.

At 7:20 P. M. he vomited 12 ounces of blood; at 8:15 4 ounces; at 8:50 he expelled the saline solution from the rectum with about 16 ounces of tarry blood. Between 9 and 10 P. M. he lost 23 ounces by the mouth and 5 more from the rectum.

Between 10 P. M. and midnight he lost 12 ounces by the mouth. His pulse became weak and his skin and mucous membranes much blanched. There was very little or no air hunger and his mind was clear. He was given a saline venous infusion of 60 ounces. Between midnight and 6 A. M. on January 3 he lost 95 ounces in all. He became pulseless with irregular respirations and broke into a cold sweat. His mind was clear nearly to the end. He died at 6 A. M.

The pulse rate of 118 when he entered the hospital rose till it reached 140 at midnight; after this it could not be counted accurately. The respirations rose from 24 to 36. The temperature rose from 99° F. to nearly 101° F.

According to the figures here given he bled 207 ounces. This is a very large bleeding, even after allowing for inaccuracies in his own statement, the nurse's measurements, and the fact that the 60 ounces of saline which was put into his veins probably reappeared as blood. Besides this large external bleeding the stomach and intestines were found full of blood at autopsy.

Post Mortem Examination, done 12:30 P. M., January 3, 1900. Liver enlarged, surface irregular, on section shows extreme cirrhosis. Esophagus shows a pinhead aperture in a varicose vein 2 inches above the cardia. The veins in this region are considerably enlarged. Stomach and intestines contain fluid and clotted blood. Spleen is enlarged and firm. The pulp is of normal appearance.

Kidneys are enlarged. Show chronic diffuse nephritis. There is a retention cyst and a white infarct in the right.

Here, then, is a case of chronic productive inflammation of the liver causing death in the 25th year.

129 East Sixtieth Street.

Experimental Contribution to the Study of the Etiology and Pathogenesis of Rickets.—Antonio Iovane and Salvatore Forte have carried out experiments on animals with a view to finding out some of the etiological factors in rickets. Believing that intestinal autointoxication was one of the principal causes of the changes in the bones they injected into animals watery and alcoholic extracts of the feces of babies suffering from rickets, dyspepsia, and gastroerteritis, and produced in them disturbances of nutrition that seem to be identical with those found in rickets. The bony alterations were in outward appearance identical with those of rachitic children. The epiphyses were increased in size, and the long bones showed the same curvatures, the animals wabbling in their walk and the stomach hanging down to the ground. There was a marked softening in all the bones, the cartilage was thickened, and cartilage cells were found infiltrating the spongy bone. All the other histological lesions greatly resembled those in rachitic children. The amount of lime salts in the bones was diminished. The authors believe that one of the principal causes of rachitis is the absorption of the products of bad digestion. While the condition is not solely due to this cause and may result from several factors, this is an important one in producing it. They believe that the process is a sort of arrest of function in the forces which produce the transformation of materials into bone substance.—*La Pediatria.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 28, 1908.

THE SIGNIFICANCE OF THE GASTRIC MUCUS.

A NORMAL fasting stomach contains very little or no mucus, as the secretion of the latter is principally connected with the digestive period. After a test-meal, therefore, we should always find a moderate amount of mucus in the gastric contents under normal conditions, while any deficiency of it at this time must be considered abnormal.

In the February number of the *American Journal of the Medical Sciences* J. Kaufmann discusses the significance of the lack of mucus after test-meals, basing his views on the examination of several thousand cases. He has found that the amount of mucus is not proportional to the amount of gastric juice. In certain cases of achylia gastrica he found increased quantities of mucus and in others none at all. On the other hand, although cases of hyperacidity, as a rule, showed a lack of mucus, he observed cases of hyperacidity with increased mucus. The familiar symptoms of gastric irritation (burning, gnawing sensation, etc.) which usually occur in patients suffering from hyperacidity he found most pronounced in persons whose stomach contents were entirely free from mucus after a test-meal. When he found in other cases the same symptoms, with no excess of acidity, or with even subnormal acidity, together with a lack of mucus, he became convinced that the latter played a role in the etiology of the symptoms in both classes of cases. He relieved all the patients of their symptoms with silver nitrate lavage (using solutions from 1-5000 to 1-1000) and found the mucus increased after treatment, while the acidity remained the same, became lower, or at times even higher. This was further evidence that the lack of mucus accounted to some extent for the suffering, and that silver nitrate, as demonstrated by Pawlik years ago, increased the flow of gastric mucus.

No matter what the cause of the lack of mucus, whether due to diminished secretion, or whether it is dissolved or digested after secretion, Kaufmann holds that the lining of the stomach is thereby deprived of its protective agent. He believes the latter causes no symptoms if there is no gastric juice or gastric juice of low acidity, but if there is an active gastric juice or one of high acidity it will cause symptoms. He contends that the lack of mucus is one of the primary disturbances in the development of gastric ulcer, depriving the mucosa of its protection against harmful influences, particularly agaist the digestive activity of its own secretions. Kaufmann, while not underestimating the dietetic and medicinal treatment of simple ulcer, does believe that a treatment (silver nitrate lavage) which brings about an increase of gastric mucus helps to cure the ulcer. His findings corroborate clinically what Turck observed experimentally. The latter studied the factors concerned in the healing of artificially produced ulcers and demonstrated a great increase of mycogen cells during the process of repair.

RADIAL ARTERIOSCLEROSIS.

THERE has been much discussion as to what inferences one is justified in drawing with regard to the condition of the general arterial tree or of special central vessels, from the condition of the radial artery. To gain information on this point Thayer and Fabyan (*American Journal of the Medical Sciences*, December, 1907) undertook the study of the radial arteries in a series of consecutive post mortems in cases which had previously been observed clinically, at the same time examining bits of aorta just above the valves, and at a point just above the origin of the mesenteric artery, as well as a piece of the mesenteric vessel itself just below its point of origin.

Their material consisted of sixty-one cases, the ages of the subjects at death varying from fifty-six days to eighty-three years. They found the radial artery varied greatly in its general characters at different ages, the microscopical picture altering progressively with the age and growth of the individual. The changes were especially striking in the intima and most marked in the fifth decade when there was firm connective tissue in the intima and media. We thus see that it may often be difficult to draw a sharp line between the normal and the pathological radial artery, for what is normal at fifty would be pathological at thirty. They found that the radial was usually palpable after the twentieth year and became a firm tube after the fiftieth year. In the majority of cases in which they found anatomical thickening they had previously diagnosed it clinically, showing that a thickened vessel becomes evident to the palpating fingers.

Although the normal structure of the aorta and mesenteric artery is in some respects different from that of the radial, Thayer and Fabyan found the changes in their intima and media in the main identical with those in the radial. The connective tissue thickening was also especially noticeable in the fifth decade. In the mesenteric artery they found calcification less frequently than in the radial, but they encountered there plaques with fatty softening of the deeper layers of the intima and superficial proliferation, which were never found in the radial. In the aorta regressive changes were particularly prone to be in the form of necrosis with fatty changes and softening.

As a result of these studies one may say that when one finds an undue thickening of the radial artery, analogous changes will usually be found in the mesenteric artery and aorta. An unduly palpable radial indicates a strong possibility of the existence of regressive changes (calcification, atheroma) in some other part of the body, and it thus may be regarded as a signal of danger.

RATS.

In Great Britain and in its colonies and dependencies the rat is to be proceeded against without mercy. The league formed recently in London having as its object the extinction or perhaps it might be wiser to say the suppression of vermin, directed chiefly against the rat, is an imperial idea. The aims of this ambitious society were well set forth by that eloquent orator Sir James Crichton-Browne, the gist of whose declamations were "*delendus est mus decumanus.*" Unremitting war is to be waged against the brown rat, for in these days the black rat is almost a negligible quantity.

The Public Health and Marine Hospital Service of the United States is always prompt in investigating new sanitary measures likely to be of general benefit, and if such are found to be really good, of recommending their adoption. This has been the case in regard to the rat. The crusade against this dangerous rodent in San Francisco has been particularly vigorous, poisons of various kinds having been employed freely. There should be favorable opportunities in San Francisco to give trials to some of the bacteriological methods which are widely lauded in Europe, but which as yet have not been sufficiently put to the test to warrant any definite statements as to their efficacy. It is not only in San Francisco itself that energetic action has been taken against the rat. Oakland, Point Richmond, and Emeryville, Cal., are making equally strong efforts to oust the offending rodent and to provide effective defensive measures against its ingress. Buildings and stables are being rendered rat proof, and the use of metal garbage cans, in place of wooden utensils, has been enjoined.

Now that it has been proven that rats are in more ways than one a real menace to the health of the community, it is right and fitting that no reasonable and feasible steps should be spared, which are calculated to abolish or abate the pest of rats. Perhaps there are few, if any, who will believe that rats can be wholly extirpated, but, on the other hand, it is obvious that their numbers may be greatly decreased. They are always a nuisance of the first order, and as carriers of plague a source of public danger. From the standpoint of health they possess no redeeming qualities and the more quickly a great diminution in their numbers is effected the better it will be for everybody. It only remains now to discover the most effective means of wholesale destruction of those dangerous animals.

Traumatic Appendicitis.

Among the multifarious causes that have been alleged as being operative in the etiology of appendicitis, direct trauma has not received a great deal of attention. Still not a few cases are on record in which blunt violence in the neighborhood of the appendix has been immediately followed by inflammation of the organ, though various opinions are held as to the precise manner in which this effect was produced. In ten cases collected by Neumann it was found at the operation that nine of the patients had harbored fecal concretions in their appendices and this fact has been regarded by that author as of great significance in the causation of the inflammation, the assumption being that as the result of the sudden rise in intraabdominal pressure about the appendix the concretion occasioned a lesion of the mucous membrane through which infection readily took place. Sonnenburg is more inclined to regard the trauma as the incidental factor which causes a previously latent process to become active and is furthermore of the opinion that fecal concretions discovered at a subsequent operation are probably a secondary result of adhesions forming in consequence of the injury and giving rise to stagnation of the contents of the appendix. Sprengel also holds the view that the trauma calls into activity a preexisting process and that the concretions are of little etiological moment. The most recent case of this sort reported is one described by Ebner (*Berliner klinische Wochenscrift*, March 2, 1908), in which a young man who previously had been entirely free from any abdominal symptoms suddenly developed an acute appendicitis immediately after having received a violent blow in the right iliac region from the handle of a tool he was using. At the operation some weeks later an encapsulated abscess was found with a concretion lying free in its cavity. After an elaborate analysis of the possibilities, too long for reproduction, the author reaches the conclusion that the appendix was previously healthy but contained a concretion which on the occurrence of the trauma injured the mucosa and permitted the entry of microorganisms leading to the acute inflammation.

Nutmeg Poisoning.

Poisoning by the oil of nutmeg is a comparatively infrequent occurrence, although perhaps not so rare as is commonly supposed. Dr. Wallace, a few years ago, made somewhat extensive investigations into the matter, and concluded that cases of poisoning resulted exclusively from the use of the crude nutmeg or mace. Prof. A. R. Cushny gave an address on the subject before the Therapeutical and Pharmacological Section of the British Royal Society of Medicine on January 28, in which he said that as far back as 1576 Lobelius related a case in which a woman was rendered delirious by the ingestion of nutmeg, used probably as an abortifacient, although, according to Prof. Cushny, it does not seem to have this action. The symptoms are drowsiness, stupor and diplopia; delirium is often present, and on occasions the first symptom is burning pain in the stomach, precordial anxiety, or giddiness. In the case of a boy who died from the effects of eating two nutmegs the symptoms resembled those caused by cannabis indica. The speaker demonstrated that a powerful poison was contained in the oil of nutmeg, and stated that from experimental work he had come to the conclusion that the symptoms were to be attributed to the action on the central nervous system. This is depressed but exhibits some indications of stimulation in the form of restlessness, slight convulsive movements, and tremor. The oil also exerts a marked local action, whether given by the mouth or hypodermically. Another speaker, Dr. J. Gray Duncanson, was of the opinion that the oil of nutmeg might act as an abortifacient, and mentioned the case of a woman who aborted after taking, among other things, a nutmeg ground and suspended in gin. Nutmeg poisoning is given very scanty recognition in British medical literature, and is not very fully discussed in American works on toxicology. However, the subject is interesting from its very infrequency, as well as from the fact that opinions are divided with regard to the action of the substance as an abortifacient.

The Pathogenesis of Gallstones.

In 1905 Gerard showed that when the acid bile salts and cholesterin were added to artificial media, and the latter were inoculated with typhoid or colon bacilli, the cholesterin was precipitated. Since then other investigators have made similar experiments and obtained analogous results. In an article in the *Wiener klinische Wochenschrift*, of February 13, 1908, A. Exner and H. Heyrovsky, endeavor to show the reason for this precipitation. Various samples of filtered and sterilized human and ox bile were inoculated with colon bacilli. A chemical examination before and five days after inoculation showed that the acid bile salts were considerably diminished after inoculation, *i.e.* were partly decomposed and that cholesterin had been precipitated. The same occurred after a bouillon-bile mixture was inoculated with colon bacilli. Remembering that cholesterin is soluble in the acid bile salts they concluded that the decomposition products of the latter did not dissolve cholesterin. Therefore the more of the acid bile salts that was decomposed the more cholesterin was precipitated. They made further experiments to ascertain to what degree the various bacteria caused the disintegration of sodium taurocholate and glycocholate. They found that at the end of five days the typhoid bacillus had decomposed more acid bile salts than proteus, pyocyaneus, *Bacterium coli, Bacterium friedländer, Staphylococcus aureus,* or streptococcus. In the order mentioned each of these decomposed a little less of the acid salts than the other, the streptococcus being the least powerful in this respect. As most gallstones consist mainly of cholesterin, and as precipitated cholesterin tends to the formation of stones, it becomes clear that those bacteria which cause the greatest disintegration of the acid bile salts will play the most important rôle in the formation of gallstones. The bacteria, on the other hand, which cause but little decomposition of these salts are probably not the cause of gallstones. Thus the streptococcus, when present in the bile of cholelithiasis cases, must be considered the cause of a secondary infection rather than an etiological factor in the formation of the stones.

The Opsonins in Diagnosis.

Although the determination of the opsonic index has not proved either as necessary or as practical for purposes of control in vaccine therapy as it was at first expected, the method is one that has many theoretical bearings and forms an important step in the investigation of the problems of immunity. It has already established itself as a useful adjunct to the resources of the laboratory worker and will probably be found of use in various directions not at first contemplated. For example, Schottmüller and Much point out in the *Münchener medizinische Wochenschrift*, March 3, 1908, an application of the method which has not yet been very widely adopted, viz., its use as diagnostic measure in disease, and as a means of differentiating closely allied groups of microorganisms. Inasmuch as the index of an individual suffering from infection with a definite organism is either higher or lower than that of a normal person, and this peculiarity is specific, if infection with a certain bacterium is suspected it suffices to determine whether or not the patient's index for this organism is different from the normal. The principle may also be reversed and used for determining the identity of a given organism by testing this with serum from a patient suffering from a known infection. The authors have employed this reaction with great advantage in several instances of obscure gastrointestinal and other infections and say that it is very useful clinically since it appears early in the disease and in very mild cases, that is, before the agglutination reaction is available, and in instances where this would be very slight. By its means they have been able to determine the pathogenicity of an intestinal organism culturally extremely close to the colon bacillus, and have demonstrated the harmlessness of the so-called Jäger form of the diplococcus of meningitis.

The Problem of Disinfection.

Prof. H. Kenwood, a recognized British authority on disinfectants and on disinfection generally, recently read a paper on the subject in London. Among other valuable information he gave was the fact that there is an advantage in the use of disinfectants in a warm condition. The physical conditions under which germicidal tests are made are of greater importance than is usually thought. The atmospheric temperature is of great importance. A precise temperature, 20° C., has been fixed by the Lister Institute as of necessity, if strictly comparable results are to be obtained. In regard to disinfecting rooms which have been occupied by persons suffering from infectious diseases, Prof. Kenwood appeared to be in agreement wth the custom followed in some parts of America not to disinfect rooms at all unless the patient had been detained in them for a long period. From the standpoint of efficiency there can be little to choose between different methods of disinfection, provided that it is recognized that they represent but one step of several which are necessary for the complete disinfection of the room and its contents, and that the most important of these steps are the washing down with soap and a disinfecting solution of all those surfaces on which dust, and with it germs, can settle, and the removal, for steam disinfection, of all articles into which germs can penetrate. It is somewhat curious that as yet we have no exact knowledge as to the efficiency of various disinfectants, nor indeed with regard to the exact value of disinfection in general. So far as the disinfection of rooms is concerned, there is considerable doubt with respect to its value as a means of preventing the spread of disease. Probably it is not money wasted to disinfect rooms, and as long as there is a doubt on the subject, it will be best to be on the safe side and to continue to disinfect.

News of the Week.

The State Anti-Tuberculosis Exhibit. — The Rochester Public Health Association will conduct an anti-tuberculosis campaign from March 30 to April 3 inclusive. The traveling tuberculosis exhibit of the State Department of Health will be held free in Convention Hall, and each day there will be lantern lectures at 3 and 8 P. M. Among the lecturers will be Mrs. James E. Newcomb, president of Stony Wold Sanatorium; Dr. John B. Huber, Dr. Lewis Gregory Cole, Professor George M. Forbes, Professor C. W. Dodge, Dr. J. Franklin Bock, Dr. Albert C. Snell, Dr. A. C. Root, Dr. Francis E. Fronczak, Miss Sophia F. Palmer, Dr. S. A. Knopf, Health Commissioner E. H. Porter, Mr. Homer Folks, Dr. W. R. Taylor, and others. All the lectures will be free and open to the public. The secretary of the association is Dr. M. E. Leary.

For a Public Health Institution in Baltimore.—A large delegation from the Medico-Chirurgical Faculty of Maryland was given a public hearing last month by the legislature at Annapolis in favor of a bill appropriating $100,000 for the erection of a public health institute and medical library building in Baltimore.

Folsom Fund of Harvard University.—The fund collected by the friends of the late Professor Charles Follen Folsom of the Harvard Medical School amounts to more than $10,000, and will probably be used to found in the school a fellowship in hygiene or mental diseases. Professor Folsom was graduated in 1862 and for nearly twenty-five years was a member of the faculty. From 1891 to 1903 he was one of the board of overseers.

New Isolation Building of German Hospital.—Last Saturday the new isolation building of the German Hospital for the care of patients with contagious diseases was formally opened. The building is a two-story structure containing sixteen rooms and was erected at a cost of $30,000, the greater part of which was given by Jacob Ruppert. The rooms are divided into groups of three, each group having its own bathroom, pantry, kitchen, nurse's room and telephone. They can be washed from floor to ceiling with hose and disinfectants, and each room has its own ventilating flue communicating with a chimney in which the air is sterilized by heat before being allowed to escape.

Protest Against Quarantine.—Governor Magoon is said to have announced his intention of protesting against the establishment of an American quarantine against Cuba on April 1 on the ground that it is a violation of the convention between the United States and the Latin-American republics. This provides that no quarantine shall be established unless yellow fever is reported within five days of the sailing of a vessel.

American School Hygiene Association.—The second annual congress of this society will be held in Atlantic City on April 17 and 18, 1908, and a long list of topics relative to the welfare of school children has been prepared for discussion.

Lumières Process of Color Photography.—In its issue of March 10 the *Münchener medizinische Wochenschrift* supplies as a colored supplement to an article on the above subject by Wilms and Eggenberger reproductions of two plates made by this process. One picture is of a cancer *en cuirasse*, and the other of senile gangrene of the leg, the reproductions being made by the ordinary three-color process. The merit of the procedure as applied to illustrative purposes consists in the fidelity with which the colors of the subject are reproduced, and in the simplicity with which the colored picture to be copied is obtained.

Street Railway Fatalities.—The report of the Public Service Commission shows that during February there was a considerable decrease in the number of persons killed as the result of street railway accidents. For this month the total number of those injured was 2,157, as opposed to 2,500 for January and 1,937 for December. The number of killed was 26, while for the two preceding months the figures were 44 and 51 respectively.

Death After Tonsillotomy.—The death of a four-year-old child from hemorrhage after tonsillotomy is reported from one of the special hospitals in this city.

Christian Science Healers Held.—A coroner's jury after investigating the circumstances attending the death of a farmer dying at Ramsey, N. J., while under the care of two Christian Science healers from this city, held the men responsible for the death and they were arrested. At a hearing before the county judge in Hackensack they were released under $500 bail each.

Christian Science in Maryland.—After a long contest the Maryland State Senate on March 19 passed a bill preventing Christian Scientists or faith healers from practising in Maryland without the diploma of regular physicians. The bill has already passed the House.

The Gibbs Prize of the New York Academy of Medicine has been awarded to Dr. Norman Edward Ditman for an essay on the Etiology, Pathology, and Therapeutics of Diseases of the Kidneys.

Against Opium in China.—As a part of its campaign against the habitual use of opium the Chinese government has issued an imperial decree ordering the governors and viceroys to restrict the cultivation of opium in consideration of the reduction of importations of the drug from India.

American Medico-Psychological Association.—The sixty-fourth annual meeting of this organization will be held in Cincinnati, Ohio, May 12 to 15, 1908, under the presidency of Dr. Chas. P. Bancroft. The secretary is Dr. Chas. W. Pilgrim of Poughkeepsie, N. Y.

Western Massachusetts Homeopathic Medical Society.—At a meeting of this organization, held in Springfield on March 18 the following officers were elected: *President*, Dr. E. W. Capen of Monson; *Vice-Presidents*, Dr. S. A. Lewis of Springfield, and Dr. T. P. Putnam of Springfield; *Secretary and Treasurer*, Dr. J. B. Comins of Springfield.

Otoe County (Neb.) Medical Society.—At the annual meeting of this society held in Nebraska City on March 7 the following officers were elected: *President*, Dr. A. P. Ginn; *Vice-President*, Dr. M. M. MacVean-Edmonds; *Secretary and Treasurer*, Dr. Frank S. Marnell.

Autauga County (Ala.) Medical Society.—This society, at its annual meeting held in Prattville on March 7, elected the following officers: *President*, Dr. J. E. Wilkinson, Sr.; *Vice-President*, Dr. J. W. Hagler; *Secretary and Treasurer*, Dr. J. E. Wilkinson, Jr.

Yellowstone County (Mont.) Medical Association.—The officers of this society elected at the meeting held in Billings on March 8 are as follows: *President*, Dr. James Chapple; *Vice-President*, Dr. Andrew Clark; *Secretary*, Dr. L. W. Bishop; *Treasurer*, Dr. Carl Shulin.

Northeast Arkansas District Medical Society.—The following were elected as officers at the meeting of this organization held in Jonesboro on March 11: *President*, Dr. L. H. Hill of Greenway; *Vice-President*, Dr. W. J. Robinson of Portia; *Secretary*, Dr. Olive Wilson of Paragould.

Ontonagon County (Mich.) Medical Society.—The annual meeting of this society was held in Ontonagon on March 4, and the following officers were elected: *President*, Dr. J. S. Nitterauer; *Vice-President*, Dr. E. J. Evans; *Secretary*, Dr. E. W. Knowles; *Treasurer*, Dr. W. B. Hanna.

Silver Bow County (Mont.) Medical Association.—The following officers were elected at the meeting of this society held in Anaconda on February 26: *President*, Dr. W. L. Renick; *Vice-President*, Dr. T. C. Witherspoon; *Secretary*, Dr. Phoebe Ferris; *Treasurer*, Dr. N. Smetters.

Wharton and Jackson County (Tex.) Medical Association.—This association elected the following officers at its annual meeting held in Wharton on February 23: *President*, Dr. W. B. Huvey of El Campo; *Vice-President*, Dr. G. L. Davidson of Wharton; *Secretary and Treasurer*, Dr. A. L. Linecum of Louise.

The Cincinnati Academy of Medicine at its annual meeting held on March 2 elected the following officers: *President*, Dr. Wm. Gillespie; *Vice-Presidents*, Dr. R. B. Hall and Dr. Stephen C. Cone; *Secretary*, Dr. Mary Keyte Isham; *Treasurer*, Dr. A. G. Drury; *Librarian*, Dr. Arch. I. Carson.

American Gastroenterological Association.—The eleventh annual meeting of this organization will be held in Chicago June 1 and 2, 1908, under the presidency of Dr J. P. Sawyer of Cleveland. The secretary is Dr. Charles D. Aaron, 32 W. Adams avenue, Detroit, Mich.

Obituary Notes.—Dr. William Bradford Eaton of Haverford, Pa., died at Bryn Mawr, Pa., on March 17 of septicemia acquired at a post-mortem examination, at the age of thirty-nine years. He was graduated from Wesleyan University in 1889, and from Haverford College in 1890. He pursued medical studies in the University of Berlin and later became pathologist to Jefferson Hospital and to the Bryn Mawr Hospital. He was registrar to the Board of Health of Delaware County.

Leonardo Da V. Judd died at Philadelphia on March 18 at the age of sixty-seven years. He was graduated from Jefferson Medical College in the class of 1877.

Dr. Frank B. Bysfield of St. Louis died on March 9 at the age of sixty years. He was born in Rocheport, Mo., and served through the Civil War in the Ninth Missouri Cavalry.

Dr. E. H. Lathrop of Hastings, Mich., died on March 7 of nephritis at the age of sixty-nine years. Dr. Lathrop served through the Civil War and for eleven months was a prisoner in Andersonville. He had practised in Hastings since 1871.

Dr. E. F. Richardson of Onaga, Kan., died on March 12 at the age of forty-five years. He was born in Smith County, Va., and was graduated in medicine in Kansas City in 1887. In that year he began practice in Onaga and remained until his death.

Dr. J. M. Sadler of Montgomery, Ala, died suddenly of apoplexy on March 7 while attending a meeting of the Montgomery Medical Society. Dr. Sadler was born in Rockhill, S. C., in 1850, and received his medical education at Tulane University, New Orleans. He practised for a time in Uniontown, Ala., but removed to Montgomery in 1895.

Dr. Charles F. J. Kennedy of Springfield, Mass., died on March 12 of gastric ulcer at the age of forty-one years. He was born in Philadelphia and was graduated from the University of Pennsylvania Medical College in 1891, and at once began practice in Springfield.

Dr. Frank L. Benedict of Portsmouth, N. H., died on March 14 at the age of fifty-two years. He was a native of Great Barrington, Mass., and was graduated from the New York Homeopathic Medical College in the class of 1879 and had practised in Portsmouth for twenty-three years.

Dr. John C. Cook of Chicago died on March 21 at the age of fifty-eight years. He was a native of Kentucky and was graduated from the Northwestern University Medical School in 1880, since which time he had practised in Chicago.

Dr. S. M. Carrigan of Hope, Ark., died suddenly on March 9 at the age of fifty-two years. He was graduated from the Missouri Medical College at St. Louis in 1807 and was president of the Arkansas State Medical Association.

Dr. John A. Wilson of Nickerson, Kan., died on March 1 at the age of fifty-seven years. He was a native of Ohio and was graduated from the Kentucky School of Medicine at Louisville in 1881. He had practised in Nickerson since 1887.

Correspondence.

OUR LONDON LETTER.

From Our Special Correspondent

ROYAL SOCIETY OF MEDICINE—FIRST ANNUAL MEETING—INFLUENZA—MEDICAL INSPECTION OF SCHOOL CHILDREN—STATE REGISTRATION, NURSES, MIDWIVES—OBITUARY.

London, March 6, 1908

The Royal Society of Medicine held its first annual meeting on Tuesday and the report may well gratify the advocates of amalgamation. The total number of Fellows is now 2,025 and there are more than 600 members of sections. The treasurer's report is just as satisfactory—surplus of assets over liabilities £39,683, excess of income over expenditure during the six months £778. During the last three months 317 Fellows have been elected who had not been previously connected with either of the amalgamating societies. A vote of thanks to the president, Sir William Church, for his services in establishing the society on the present basis and his conduct in the chair, was unanimously adopted.

Influenza continues to claim many victims, and the recoveries are often characterized by protracted convalescence, to say nothing of relapses and the many complications. The epidemic seems to have spread over the whole country. Reports from the large towns are constantly issued, but I also hear frequently of small villages providing a number of cases. Here in London there has been a steady increase for a couple of months, and pneumonia, as would be anticipated, has caused more deaths than the average. At the same time, those from bronchitis have been below the average, though the numbers have in some weeks been above. The mortality from influenza during the last four weeks has been 32, 34, 84, 126.

The Board of Education seems to have a curious idea of what medical inspection of children means. The schedule issued by this authority for the guidance of the doctors comprises the family history, while the personal condition of the child is required to be examined according to the points laid down in twenty-four separate paragraphs. The board considers that the "inspection of each child should not occupy on the average more than a few minutes." Yet the board says the inspection should "take account of the following matters: (1) Previous disease; (2) general condition and circumstances—height, weight, nutrition, cleanliness, as well as clothing; (3) throat, nose, and articulation; (4) external eye diseases and vision testing; (5) ear disease and deafness; (6) teeth; (7) mental capacity—normal, backward, or defective, and (8) present disease or defect."

I should like to make the person who drew up this program accompany me to a school and write down to my dictation the remarks I might make on each point and see how many minutes it took him to do so.

Registration, notification, and State regulation are still advocated by many as panaceas for the troubles of doctors as well as patients. The profession was induced to advocate the registration of midwives. At any rate, consulting obstetricians urged the scheme and many general practitioners who could afford to give up midwifery followed their lead. Others, who saw objections and had reason to fear loss of income, were too apathetic to organize resistance and are now complaining that the certificated midwives are taking no small part of their practice. Moreover, they declare that this new order of practitioner, under the control of the Central Board, on which eminent accoucheurs sit, is interfering with the treatment of patients and undermining the authority of the family doctor when he is called in. I have heard some remarkable instances of this, which make me think that the doctors have not

such great cause for rejoicing at the result of the midwives' registration.

Another cry of the kind is now being raised, viz., for the State registration of nurses. It is said and may well be believed that all the self-governing associations desire registration, though when its advocates add that the whole medical profession is in favor of it some doubts may be entertained. The apathy of the majority may again allow the enthusiasts to carry out their scheme, and it is possible, too, that in such case not a few vain regrets will be expressed when it is too late.

There was a public meeting recently to advocate registration "as a matter of national importance" and to support the bill which has been brought into Parliament for this purpose. At this a letter was received from Sir Victor Horsley expressing sympathy with the movement, and Dr. Langley Browne, a direct representative of the registered practitioners on the General Medical Council, attended and spoke in its favor. He professed he could not understand the opposition to it as the only way by which trained nurses could distinguish themselves from the untrained and unfit. There are, nevertheless, many who do understand the opposition and who ask whether a hospital training is a guarantee of character and an assurance that the nurse will obey the doctor instead of circumventing him. On the whole, I cannot admit that Dr. Browne really represents his constituents. Still less that another medical man who followed him was justified in saying that the profession has "plumped" for registration.

Dr. Hyslop, the resident physician of Bethlehem Hospital, spoke of the claim of mental nurses to separate recognition in any scheme of registration, and related how, as recommended by the select committee of the House of Commons in 1905, the Medico-Psychological Association had taken steps to provide a register of asylum-trained nurses, though he added that some form of registration of asylum nurses had been in existence for many years. The training for the association's certificate extends over three years and must be in not less than two institutions. He claimed for asylum nurses recognition as specially fitted for the care of mental cases.

It should be observed here that Bethlehem and some other institutions have admitted nurses trained in general hospitals who desire to add to their knowledge by some experience in mental disorders, and it is obvious that a general hospital training affords no guarantee of efficiency in the care of the insane.

There was yet another special claim put forward at this public meeting, viz., one for nurses in fever hospitals. The question of their efficient training is of no slight importance, but if specialties in nursing are to be multiplied is the scheme for general registration feasible? The opposition, too, are saying that with these specialists we might be worse off than we are.

Dr. Mapother, formerly president of the Royal College of Surgeons in Ireland, died on Tuesday, aged 72. After a very distinguished career in Ireland he came and settled in London in 1888. He was a graduate of the Royal University, 1857, with highest honors and the gold medal, and took the F.R.C.S.I. in 1862, became consulting surgeon to St. Vincent's Hospital and St. Joseph's Hospital for Children, professor of physiology at the college, examiner at the Queen's University, and president and vice-president of several Dublin societies. He was surgeon to the Lord Lieutenants of Ireland from 1880 to 1885. He took the Carmichael prize in 1868. His "Manual of Physiology" ran through three editions, and his "Lectures on Public Health" was as successful. He was recognized also as a learned dermatologist, his lectures on that subject reaching a second edition in 1875 and a further series of "papers" on it in 1899. Among other contributions I may name the articles on skin diseases in Quain's Dictionary of Medicine.

Mr. Reginald Harrison died on Friday at the age of 70. He was a Bart's alumnus, took the M.R.C.S. in 1869 and the Fellowship in 1866. He had been surgeon to the Liverpool Royal Infirmary and lecturer on anatomy and surgery in the school. He had also been professor of clinical surgery at the Victoria University. He became Hunterian professor of pathology and surgery of the Royal College of Surgeons, a member of the Council, and in due course served as vice-president. He had also been president of the Medical Society of London, vice-president of the Medico-Chirurgical Society and Honorable Fellow of the American Surgical Association, the Chicago Academy, and some foreign societies. He was consulting surgeon to St. Peter's Hospital and other charities. His work on "Surgical Disorders of the Urinary Organs" passed through several editions, and his works on lithotomy, lithotrity, the prostate, and allied subjects are well known. He was a contributor to several important works, including *Ashurst's Cyclopedia* and the *XXth Century Practice*, *Liverpool Reports*, and the *Clinical Journal*.

Sir Alfred Cooper, another vice-president of the Royal College of Surgeons, died on Tuesday at Mentone, aged 70. He was consulting surgeon to the West London, St. Mark's, and the Lock Hospitals, surgeon to the Royal Society of Musicians, had been surgeon to the late Duke of Edinburgh (Saxe-Coburg and Gotha), and a surgeon-major in the volunteers. He qualified in 1861, took F.R.C.S. in 1870, and was vice-president in 1903. His work on "Syphilis and Pseudo-Syphilis" went through two editions, as did his "Diseases of Rectum and Anus." He contributed various papers to the journals, served as president of the West London Medico-Chirurgical Society and vice-president of several other associations. He was an honorary member of the St. Petersburg Medical Society and was made chevalier of the Order of St. Stanislaus, Russia, in 1874. In 1902 he was knighted.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE CONJUNCTIVAL TUBERCULIN REACTION—COLD AND TETANUS—GASTROENTEROSTOMY WITH A PERMEABLE PYLORUS.

PARIS, February 5, 1908.

AT the meeting of the Académie de Médecine, Calmette urged the advantages of his conjunctival reaction in tuberculosis, and emphasized its value in the combat against tuberculosis as a disease of the masses. He stated that the procedure sufficed to determine with almost absolute accuracy the existence of tuberculous lesions at a period before any clinical signs were apparent. The tuberculin used should have been purified by three precipitations with alcohol, followed by drying in vacuo. The powder thus obtained was redissolved in physiological salt solution in the proportion of 1 to 100. A single drop of this solution placed at the inner angle of one eye produced the characteristic reaction in tuberculous individuals. For use in children, a 0.5 per cent. solution was preferable. In describing the reaction, he said that it varied very much in intensity, sometimes being very evident in four or five hours, and disappearing within twelve or sixteen hours. Sometimes it did not appear until twenty-four or forty-eight hours had elapsed, and it then lasted for five, or even six, days. It had been tried on thousands of cases, and seemed to have demonstrated its reliability and harmlessness, while the simplicity of its application entitled it to adoption by clinicians. It was, furthermore, useful in facilitating the decision as to what should be done with a patient, and afforded the best of arguments for requiring either his isolation or his removal to the country or a sanatorium. The method would also be useful in dealing with the children of tuberculous patients, and there was no doubt that it would be of the greatest value in the restriction of the disease among the population at large.

This paper was followed by an animated discussion, in the course of which Prof. Delorme criticised the speaker's conclusions. He considered that Calmette's views should not be accepted, as they involved many disadvantages and might even be dangerous. The ophthalmo reaction had no value except as one feature of a series of symptoms and frequently gave rise to errors in interpretation. Its use by military surgeons was contraindicated, and while the ocular complications sometimes caused were rare, they were sufficiently serious to restrict the applicability of the procedure. In replying to Delorme, Calmette said that he considered that the diagnosis of tuberculosis should not be concealed either from the patient or from his family, particularly now that, thanks to new methods, it might be made sufficiently early to afford a maximum chance of cure. He quoted the results obtained in 14,000 cases, reported by clinicians of many different countries, which showed that the reaction is positive in 92 per cent. of cases of undoubted tuberculosis, in 61 per cent. of the suspicious cases, and in 18 per cent. of individuals apparently healthy or suffering from supposedly nontuberculous affections. As for the rare local complications, they could not in any respect be ascribed to the procedure itself, for very simple precautions sufficed to avoid them. Delorme replied to this that the ocular reaction to tuberculin was not specific. Arloing of Lyons had shown by recent experiments which were well in accord with observations on the human body that other toxins than that of the tubercle bacillus, such as the toxins of the typhoid bacillus, the diphtheria bacil-

lus, and the staphylococci, might give rise to positive reactions. Furthermore, the test was not infallible, and in a third of the cases was very disagreeable, an important reason for not employing it in the army, which was not organized to serve as a proving ground for experimental medicine.

Vincent presented an interesting paper on the influence of cold on the etiology of tetanus. Numerous observers had described cases of tetanus occurring in persons exposed to prolonged chilling, even though no traumatism was caused. Until now, no experimental evidence was available to explain this action of cold in favoring the development of the disease. Vincent had found that exposure of the entire body to cold was not a potent predisposing factor in dealing with large animals. For example, in order to obtain positive results, it was necessary to reduce to 28° C. the internal temperature of guinea-pigs. While general chilling had only a slight influence on the etiology of tetanus, the case was different with local exposure to cold. If the hind leg of a guinea-pig was held for one or two hours under a stream of cold water while the rest of the body was kept warm, and tetanus spores were then injected under the skin of the limb, the disease appeared after a very short period of incubation and killed the animal with great promptness. Local peripheral chilling, therefore, had a powerful effect on the etiology of tetanus, while the exposure of the entire body to cold seemed of little importance. This matter, therefore, might have considerable significance in regard to the origin of infectious diseases in general. Such disorders could not always be explained as the results of simple inoculation, for the pathogenic microorganism was an essential but not an all-sufficient causative factor. In studying the pathogenesis of the infectious diseases, it was necessary to accord considerable importance to the influence of various secondary factors, such as prolonged fatigue, intoxication of exogenous nature, autointoxication, traumatism, or impairment of the hepatic functions. All of these conditions, by themselves or associated, as well as cold, had an unfavorable effect on the leucocytes, restraining their normal activity and preventing them from engulfing the pathogenic microorganisms, and, therefore, permitting these to flourish.

At the meeting of the Societié de Chirurgie, the subject for discussion was the efficacy of anastomoses between the stomach and intestine when the pylorus was permeable. Pierre Delbet presented the stomach of a dog that had been subjected to gastroenterostomy. Mechanically, the operation was perfect, but in the living animal no food or liquid escaped from the stomach through the artificial opening. This observation, which had been made in all the animals subjected to the operation, but with a permeable pylorus, explained why it was that in cases of moderate stenosis of the pylorus in man, gastroenterostomy did not always afford the expected relief. This was usually thought to be due to some error of technique, whereas it was really a physiological phenomenon.

An animated discussion followed the reading of this paper. The first speaker was Ricard, who thought that Delbet's observations showed that it was advisable to restrict gastroenterostomy to those cases in which the pylorus was not patent. Under these conditions, the procedure would be of service. He considered that the best method for performing the operation was that of von Ackere. The opening should be large, and be made at a point as near the pylorus and as low down as possible. Souligoux thought that the experiments reported showed clearly that in a muscular organ with longitudinal and circular fibers the contents always tended to take a longitudinal direction. After a gastroenterostomy, if the pylorus was permeable the longitudinal fibers continued to drive the food toward the pylorus, while the circular fibers tended to close the new gastrointestinal opening. Guinard thought that gastroenterostomy brought great relief and often a cure to patients suffering simply from pyloric spasms.

Monprofit, on the other hand, thought that it was not necessary for the pylorus to be obstructed in order to have gastroenterostomy prove effectual. He described several cases in which new growths or ulcers were situated on the lesser curvature, leaving the pylorus uninvolved, but in which gastroenterostomy alleviated the symptoms. Legueu had also been able to study a patient who, two years previously, had been subjected to gastroenterostomy for an obstinate dyspepsia unaccompanied by any symptoms of pyloric stenosis. The Roentgen ray examination of the stomach had shown that all of the food which was ingested was passed out of the stomach through the new opening, and in spite of the fact that the pylorus had remained permeable, nothing whatever passed through it into the intestine, everything taking by preference the new route which had been opened by the operation.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CONJUGAL DIABETES—DENTAL DISPENSARIES FOR SCHOOL CHILDREN—LARGE FAMILIES AMONG THE WORKING CLASSES—ROENTGEN RAY TREATMENT OF CHRONIC BRONCHITIS AND ASTHMA—VESICAL PAPILLOMATA.

BERLIN, February 15, 1908.

At the meeting of the Society of Internal Medicine, Senator delivered an address on conjugal diabetes, which was especially interesting for practitioners. He said that the statistics so far available were not sufficient to elucidate the question of the transmissibility of the disease. For example, in 1890, Schmidt had found twenty-six diabetic married couples among 3,200 diabetic patients, Naunyn had found 18 among 775, Poisimeau about 50 among 5,000, while he himself had found 9 among 770 private patients, and 15 among 897 dispensary patients. In gathering further statistics a point should be made of determining what was the proportion of married persons among diabetics, and, furthermore, what was the period of incubation. In the couples observed by Senator, the interval before the first patient's partner developed the disease varied from one to fifteen years. That it is possible for several cases of diabetes to have a common cause was shown by various reported instances. For example, Senator had seen a physician who had become diabetic after amputating the thigh of a patient having the disease, and not long afterward five cases appeared in the same street of a small city, the patients being an innkeeper and four habitués of the inn. That infection is possible in diabetes was shown by animal experiments, in which the disease was caused in animals by the injection of diabetic urine, gastric contents, and feces. As all of these facts, however, had no decisive value, it was desirable that practitioners should gather new statistics in reference to the question.

The suburbs often surpass Berlin itself from the standpoint of social hygiene; for example, the first forest school was founded in wealthy Charlottenburg, and this city has also been the first to establish a dental dispensary for school children. Three dentists have been appointed to give free treatment to children whose teeth are defective and whose parents are in poor circumstances.

The province of social medicine is also involved in a very interesting address delivered before the Society for Social Medicine by C. Hamburger on the question of the prevention of conception in the families of the poor. He said that every conception which did not result in increasing the number of self-supporting persons by one unit represented a loss to the nation. In order to obtain satisfactory population statistics, it was, therefore, necessary to determine in how many instances the products of conception did not become individuals reaching an age at which they were able to yield a return for what they had cost. At present an answer to this question was impossible, as adequate figures concerning abortion were not available. Every premature death and every still-birth or abortion was a drain on the resources of the workingman's family through the reduction in the mother's strength and in the buying capacity of the family, owing to the expense for midwives, funerals, and other necessaries. He himself had found that 1,042 wives of workingmen had 7,261 conceptions representing an average of 7 for each marriage, whereas among the well-to-do it was 3.5. Among the working classes, more than half the infants died prematurely, a third through death and the rest through abortion, and not quite 50 per cent. attained the sixteenth year of life. In the German Empire, in order to maintain the number of survivors constant, three conceptions per marriage would be required; four conceptions per marriage would increase the population annually by about four hundred thousand. In the combat against infant mortality, under present conditions, the most effective measure was the reduction of conceptions. Less broad measures, such as encouraging mothers to nurse and the better care of infants, while important, in the long run would be ineffectual, for the regular increase in loss corresponding to the increase in the average of conceptions proved that the support of the children exhausted the resources of the parents. The dogma of the benefits of large families should disappear, for it was evident that every increase in the ratio of conceptions was attended by still greater increase in infantile mortality. A restriction of conception would involve no danger for the State, for the diminution in births was more than compensated for by the reduction in mortality.

Immelmann read a paper before the Medical Society on the treatment of chronic bronchitis and bronchial asthma by means of the Roentgen rays. He had found that both the acute asthmatic attacks and the associated bronchitis were very favorably modified by the use of the Roentgen rays. In many cases only a few treatments were required in order to effect the desired result. He agreed with Schilling in believing that the rays influenced the mucous cells. The patients are treated twice a week, no diaphragm being used. It is probable that the effect is to cause the cells to evacuate their contents more rapidly than usual, but there is also the possibility of some connection with the eosinophile cells and the Charcot-Leyden crystals.

Before the same society, Casper spoke concerning recurrences of vesical papillomata. In sixty-four cases he had seen recurrence sixteen times. In nine of these the patients had been operated on by other surgeons, sometimes several times. In these the operation had been done by suprapubic incision, and multiple papillomata had appeared. It might be assumed that when the operation was done this way the tumor cells were squeezed into the freshly opened lymphatics, and, therefore, recurrence was more likely than when an endovesical operation was done. Accordingly, the latter seemed preferable, and he had performed it in sixty-four cases with good result. Even though recurrences occurred when this method was pursued, they could more easily be dealt with.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

MYCOSIS FUNGOIDES—ACTINOMYCOSIS OF THE LUNG—PRESSURE TREATMENT IN GENITOURINARY AFFECTIONS—OPSONINS.

VIENNA, February 12, 1908.

PROFESSOR EHRMANN presented before the Society of Physicians a patient suffering from erythrodermia. The condition had persisted for about nine months and the patient showed the following state of affairs: There was almost continuous diffuse uniform reddening of the entire surface of the body which was less pronounced on the palms, soles of the feet, and the extremities, while it was entirely absent about the genitals. The color was deep red with a shade of blue about the extremities. On inspection, and still more plainly on palpation, it was evident that the skin was edematous, slightly swollen, and moderately infiltrated. Over the chest and back it was tense, devoid of the normal markings, and somewhat shiny. On the inner surface of the thighs, in the axillary region, and about the elbows, it was thrown up in coarse plump folds and the markings were very pronounced, so that in places areas were seen resembling alligator skin. The same condition existed about the back of the neck. There were palpable glands in the inguinal, axillary, and cubital regions, as well as in the supraclavicular fossa. The hair of the head and of the pubic region had to a large extent fallen out. Physical examination showed no abnormalities, and the Calmette and von Pirquet tuberculin reactions were negative. The blood picture, however, was remarkable. At the end of October, the red cells numbered 3,900,000, the leucocytes, 21,000, the hemoglobin was 85 per cent., and the differential count showed 72 per cent. of polynuclears, 9 per cent. of eosinophiles, 3 per cent. of basophiles, and 16 per cent. of eosinophilic myelocytes. At the end of December, the red cells were 2,800,000, the leucocytes 20,000, the polynuclears 55 per cent., eosinophiles 32 per cent., lymphocytes, 11 per cent., and large mononuclear leucocytes 1.7 per cent. The pathology of the erythrodermias is still far from clear, and depends somewhat on the question of the relationship between true leukemia and the various forms of pseudoleukemia. One group is probably associated with tuberculosis; namely, Hebra's type of pityriasis rubra. A second series is composed of diffuse or circumscribed erythemas and scaliness with infiltration of the skin with leucocytes, combined with the blood picture of true leukemia. Finally, there are varieties which are difficult to classify, and include pseudoleukemia, and forms in which there is a leucocytosis but no leukemia as in the present instance, which, however, differs from most of the cases in the comparatively large number of eosinophiles, and must, therefore, be regarded as a probable example of mycosis fungoides.

Haudek has reported a case of primary actinomycosis of the lung. The patient was a cook, aged thirty-seven years, who had been sent to the hospital with a diagnosis of pulmonary tuberculosis. Both the history and the physical signs were suggestive of this condition, but on the right side of the thorax there was moderate swelling and pronounced dullness. There was also evidence of aortic compression. Roentgen ray examination showed that there was infiltration of the right upper lobe and the adjoining portion of the lower and middle lobes, and enabled the possibility of aneurysm to be excluded. In the profuse bloody sputum neither tubercle bacilli, tumor cells, nor actinomyces granules could be found. While under observation, the patient remained free from fever, a circumstance which, together with the absence of tubercle bacilli, was against the diagnosis of tuberculosis. In the course of six weeks, the swelling on the right side of the chest wall constantly increased and became very hard and tender. Later the flat surface of the swelling became red in the neighborhood of the fifth intercostal space, softened, and a fluctuating abscess the size of a walnut formed. On incision, a small amount of thick bloody pus was obtained, containing actinomyces granules, while the sputum also revealed the characteristic organisms. The patient was transferred to the surgical division for treatment.

Kornfeld has devised a method of applying pressure treatment in urology, and has demonstrated his apparatus for use in cases of prostatic affections and urethral strictures. In treating the prostate, he introduces a heart-shaped or violin-shaped colpeurynter into the rectum in the collapsed condition, and then fills it with air by means of a syringe. In doing this, by suitable manipulation of the piston vibratory or percutory impulses may be transmitted to the prostate. In place of air, water or mercury may be used. The treatment of urethral strictures is as follows: A bougie is, if possible, passed through the stricture and allowed to remain two or three minutes. It is then replaced by a similar instrument, over which a very thin rubber bag has been stretched. After this has been placed in position, the bougie is very carefully removed, so that the bag alone remains in the stricture. The latter is then very slowly filled with water or mercury by means of a syringe under only moderate pressure. The opening of the bag is clamped and it is left in the urethra for ten or twenty minutes. The effect is often evident even on the next day. In six cases of enuresis, Kornfeld applied this method with exceedingly good results.

H. W. Abelman of Chicago, by invitation, presented before the Society of Internal Medicine a discussion of opsonin determinations, in which he spoke highly of the value of this diagnostic aid, and described in detail the technique of its application.

VEGETARIANISM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—An editorial in the MEDICAL RECORD on vegetarianism some time ago was reproduced in the newspapers and caused discussion. Races and individuals differ in internal construction to an amazing extent. For instance, the small intestine varies in different races and individuals as to its size, structure, strength, and length. One man may require vegetable food with little meat; another may fare best on meat with little vegetable food, still another may live on animal food (milk or eggs) alone, but no race exists on exclusive vegetable diet. Absolute vegetarianism is impossible in man. The necessity for animal food is so great that people under stress of its need eat grubworms. In parts of China a dead cow disappears more completely than from an onslaught of wolves and vultures, for the bones are consumed as a last morsel.

Individuals capable of unusual endurance or extraordinary digestion may be accidental racial variations or "throw backs," reversions in digestion and musculature to subhuman types. Such individuals are not products of any system of dietetics. This may account more or less for the endurance tests on vegetables with little animal food. A pigeon differs in digestive apparatus from a chicken-hawk. A pigeon may live almost entirely on grain, while the hawk eats meat alone. As a rule, carnivorous animals bolt food, while the herbivora masticate thoroughly.

Why is it that some individuals subsist on skim milk, while an Esquimaux eats at one sitting ten pounds of blubber or sea moss? Nature, through instinct, appetite, experience, and the common senses, teaches every living thing what food is best. Else why are smell, sight, and taste set as guards to the portals of digestion. It is too trite to say what is one man's food is another man's poison, and it will be many a year before science finally charts out a safe system of dietetics. Medical observation teaches that the stomach often has more sense and judgment as to selection and ejection that its owner.

NEW YORK. NORBURNE B. JENKINS, M.D.

TOBACCO AMBLYOPIA

To the Editor of the Medical Record:

Sir:—Anent the views expressed by writers in recent issues of the medical and secular press on the effects of tobacco upon the human subject, it may be pertinent to suggest further inquiry on the by no means well-established toxic effects of tobacco. It is hard to say why tobacco has been selected as the general agent for inciting what is called toxic amblyopia. Is it not a fact that various toxic agents are said to be attended by varying degrees of amblyopia, and that some writers, apparently eager to ignore the effects of alcohol, have taken up the consideration of central and peripheral lesions of the optic nerve, clearly due to prolonged local disturbances of the vasomotor system, from various kinds of excesses and mechanical obstruction to nutrition, even including tuberculosis, to set forth an exaggerated view of the by no means well-established toxic effects of tobacco? In Turkey, where tobacco is inordinately used by both sexes and among all classes, the so-called tobacco amblyopia, according to competent observers, is almost unknown, and yet the daily consumption of tobacco by this portion of the Musselman race is enormous. Carefully made assays show that the smoke from Turkish cigarettes (which the Turk draws directly into the lungs) contains about double the percentage of nicotine and carbon dioxide that is found in cigars made from Havana tobacco. Does not the Moslem law religiously interdict, among other things, the use of alcohol in any form, and exact from the faithful strict observance of bodily cleanliness by morning and evening ablutions?

In a series of clinical observations which the writer reported to the Kentucky State Medical Society in June, 1895, there will be found some cases in which it was clearly apparent that the amblyopia was not caused by tobacco, but was due directly to retrobulbar neuritis. Similar cases clearly establish the fact that the symmetrical scotomata are neither diagnostic of tobacco amblyopia nor constantly present in otherwise apparently well-established cases. Is there a physician who at some time in his medical career has not been taught that the "exact symmetry of this affection is one of its marked features"; does one "always find the same amount of defect in each eye," and achromatopsic phenomena fairly attributed to tobacco alone? Are these scotomata for certain colors due to toxic influences or structural changes? It is not unreasonable for one to be more inclined, taking into consideration environments and the "eccentric" character of patients, who are said to suffer especially from this form of amblyopia, to favor some mechanical obstruction to nutrition, inflammation excited by tuberculosis, the reflex phenomena in cases of megrim, to keep well to the front the neurological elements, and not make tobacco alone chargeable for certain undeveloped or over-exaggerated types of amaurosis. A shock to the nervous system from a railroad accident has been said to be followed by the so-called tobacco amblyopic indications.

What physician, no matter how large his experience or favorable his surroundings to the proper study of the aberrations found in eye troubles, can say he is safe in the recognition and differentiation of anesthetic retinitis coincident with locomotor ataxia, the retinitis of anemia, and the multifarious forms of toxemia alone with "tobacco amblyopia"—for is it not a fact that in the majority of instances we are unable to assign a cause?

All the conspicuous symptoms of the so-called tobacco amblyopia are, in a great measure, identical with those visual disturbances which arise from axial neuritis, observed in poisoning by sulphur, bisulphide of carbon, stramonium, cannabis indica, iodoform, quinine, alcohol, and even in starvation. Is it not a fact that similar lesions and visual disturbances exist in varying degrees, more or less prominent, in nearly all organic lesions of the brain and spinal cord, in embolism, loss of blood, dementia paralytica, traumatism, syphilis, tuberculosis, epilepsy, dysmenorrhea; various forms of nephritis, miasmatic fevers, anemia, rheumatism, podagra, and grippe?

Can we so readily differentiate the varying forms of amblyopia and not be startled when we hear it stated or see it set forth in print, describing certain trophic neuroses that are unmistakably distinctive types of disease—as "characteristic effects" of the use of tobacco? Is it fair to assume, therefore, that the so-called tobacco amblyopia has any distinctive characteristics? The habit of smoking is now at its apogee. It may be taken as a rule that almost every man smokes who by idiosyncrasy is not disabled from indulgence. It may be prudential to infer that some, reasoning from their anti-tobacco standpoint, in assuming that the "weed" is responsible for a certain form of amblyopia, and, in their haste to satisfy themselves with a cursory examination, even to the ignoring of the physiological aspect and, to further their reasoning in contradistinction to anatomical facts, are sacrificing themselves on the altar of duty rather than promulgating their belief.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 12, 1908.

Diagnosis and Treatment of Exophthalmic Goiter.—The paper of J. M. Jackson and L. G. Mead is an analysis of 85 cases personally treated. Of this number 80 were women and five men. Nothing unusual is presented under the heading of diagnosis, but the authors claim that many cases are not recognized until they have become advanced. Their favorite remedy has been the more or less continuous use of the neutral hydrobromide of quinine, first proposed by Forchheimer. The acid salt does not act as well. The neutral salt is given in five-grain capsules three times a day and this is as much as can ordinarily be borne, although the authors have found patients who could take four capsules a day for a long time without the unpleasant symptoms of tinnitus. On the other hand they occasionally find a patient who cannot take more than one or two capsules a day. At the beginning of treatment patients are told that no marked effects may be seen short of a month and they must be prepared to continue it for at least two years. Great stress is laid upon this because patients become very easily discouraged if no immediate results are obtained. Usually after a week or two of treatment the pulse rate will be slowed, the thyroid diminished, and the sweating and tremor lessened. It should be continued until all the symptoms have disappeared, which may be in four months or as long as three years. The order of disappearance of the symptoms seems to be, first, the tachycardia subsides, then the sweating, then the thyroid gland diminishes, and finally the exophthalmos and tremor, the last two after only a prolonged course of treatment. In a few instances the goiter and exophthalmos persisted more or less marked after all other signs had disappeared and the patient was practically well and at work. They have never seen any bad permanent effects follow from the administration of the quinine, and the only unpleasant effect is occasional tinnitus, especially if large doses be given. It is advisable to continue the drug in small doses, one capsule three times a week during the second year, and the patients are cautioned to immediately return to former doses at the first indication of any reappearance of their old symptoms.

New York Medical Journal, March 14, 1908.

Indicanuria.—G. M. MacKee presents a general review of this subject under the heading of etiology, diagnosis, pathogeny and treatment, and adds a copious bibliography of literature, ancient and modern. The test preferred by the author is a modification of Obermayer's. The reagent consists of a stock solution of chemically pure ferric chloride in pure hydrochloric acid. Five cubic centimeters of this reagent are added to the same volume of urine in a test tube; 1 c.c. of chloroform is added to this mixture, and the tube inverted several times. If indican is present the chloroform, which rapidly settles to the bottom of the tube, will assume a blue color, the intensity of which depends upon the amount of indican in the urine. Occasionally the splitting of the potassium indoxyl sulphate is delayed, so in all negative cases it is advisable to allow the mixture to stand for several minutes before venturing an opinion. In mild reactions better contrast can be obtained by replacing the urine with water, leaving the chloroform at the bottom of the tube, or the urine may be clarified by filtration after the addition of a few drops of a saturated solution of lead acetate. Occasionally one will obtain a purplish or red, instead of a blue, reaction. This is probably due to the presence of skatoxyl compounds. The significance is the same, providing the patient has not been taking potassium iodide, which will give a red reaction with this reagent. Any doubt can be cleared up by the addition of a few crystals of sodium hypophosphite. Under the head of treatment, the author expresses a favorable opinion as to the value of sour milk, and considers that the commercial buttermilk answers every purpose.

Winter Diarrhea and Infant Feeding.—E. K. Shelmerdine believes that some cases of diarrhea occurring in infants during the winter months are due to changes produced in the milk by freezing which produces small curds floating on the top. Straining removes all this and in one case in the author's experience cured the diarrhea in half a day. The freezing is hard to avoid in winter from the ordinary method of domestic delivery. The author

says that where the milk is frozen the water in it is congealed into ice, the perfect solution of the casein in the water is disturbed, and there results a clumping of the proteid molecules which lose their solubility; on the reduction of the frozen mass to a liquid, the curds, through some chemical change brought about by the freezing, are incapable of acquiring the solubility which they formerly possessed. These minute curds cannot be broken up by pouring the milk from one jar into another, by agitation, or by heating, and are present in the final mixture. The diarrhea caused by frozen milk is not as severe nor as debilitating as that of the summer season; neither are the number of stools as great. Six to twelve stools a day is the average. There is distressing colic. The stools are green, acid, watery, and contain small cheesy masses of undigested casein; the buttocks are generally excoriated from the irritative effects of the acid stools. Treatment consists in taking the child off the milk diet for twenty-four hours, cleaning out the bowels, and giving barley water in the interim. If the condition is recognized early, correction of the underlying cause will produce a prompt subsidence without the necessity of stopping the food.

Acute Double Miliary Tuberculosis of the Conjunctiva.—A case is reported by H. F. Hansell, whose patient was a Lithuanian of 37 years, entering the United States in 1906. He had always been healthy and stated that he had had no trouble until about two months before coming under observation, when he presented to superficial external examination the characteristic appearance of trachoma. The skin of both upper lids was discolored and the lids were swollen and drooping. On the palpebral surface the resemblance was equally marked. Scattered over the conjunctiva of both upper and lower lids were numerous yellow, isolated swellings that might at first glance be mistaken for trachoma follicles. Close inspection showed that the yellow patches were not granulations or enlarged follicles. They were round or oval, the size of a grain of wheat, circumscribed and sharply separated from the adjacent membrane, yellow in color, as though they contained pus or caseous matter, slightly raised above the surface of the membrane and covered by epithelium. They were shallow, not penetrating as far as the tarsus. The pathological laboratory collected some of the material from the surface of the conjunctiva by gently scraping and reported the presence of numerous tubercle bacilli. Examination of the contents of one of the little caseous elevations had been commenced, but not completed. No signs of general tuberculosis could be detected by examination of the lungs, sputum, or urine. The preauricular or cervical glands were not enlarged. The eye grounds were healthy. V = 6/6 with — .75s. The author adds some remarks on conjunctival tuberculosis. He says that Calmette's suggestion of diagnosticating and treating such cases by applying tuberculin directly to the conjunctival sac and then determining by the reaction the presence of tuberculosis is not, in his limited experience, dependable. It was tried in the case cited with negative results; also in fifteen or twenty individuals known to be suffering with general tuberculosis the reaction was present in only one fourth.

Journal of the American Medical Association, March 14, 1908.

The Chemical Control of the Body.—E. H. Starling points out that recent investigations have proved that administration of drugs for the cure of disease is only imitating the methods employed by Nature, and that a large share of the coordination of the activities of different organs of the body is due to the production and circulation of chemical substances, strictly analogous to the drugs employed in the treatment of disease. As an illustration of this fact, he refers to secretin, the chemical substance that excites the pancreatic secretion when the food passes into the duodenum. This body can be regarded as the type of a whole group of chemical messengers, which, formed in one organ, travel in the blood stream to other organs of the body and effect correlation between the activities of the organs of origin and the organs on which they exert their specific effect. To these chemical messengers has been given the name "hormone." The chemical agents acting on the organism have been divided by Ehrlich into two classes, which may be designated briefly as the toxins and the drugs. There is one marked distinction between the two groups: The toxins cause the formation in the organism of antibodies, tending to produce immunity, while in the case of the drugs, though with some, as with morphine, a limited degree of tolerance may be produced, there is no evidence of the production at any time of antitoxic substances. The hormones, acting constantly as chemical messengers from one organ to another by way of the blood, can not produce antibodies that would abolish their function, and must necessarily, therefore, belong to the class of drug substances. Their action must also, in all probability, be ranked with the purely chemical processes. Other functions are correlated by these chemical messengers, such as stimulation of the respiratory center by carbon dioxide in the blood, the action of adrenalin on the blood pressure. Our knowledge of other hormones is as yet incomplete, but facts indicate their existence as shown in the effects of the internal secretions of the pituitary, thyroid, and sexual glands in which the relations existing between the activity of certain organs and the development and functions of others are most clearly manifest, though the chemical nature of the hormone has not yet been revealed.

Endometritis.—B. M. Anspach has critically examamined every case in which a histological examination of the endometrium was made in the gynecological department of the University Hospital from October, 1899, to October, 1907, classing the endometrium as normal only when there was no anatomical alteration recognizable grossly or by the microscope. There were 2,280 gynecological patients during this time, among them 337 cases of diseased mucosa, but only 94 occurred as clinical entities, and 243 were associated with more serious conditions requiring operation. He concludes, therefore, that one should be very guarded in promising a patient that a given uterine disease will be cured by a curettage, and that the non-operative treatment of leucorrhea by the direct application of antiseptic or caustic solutions to the uterine cavity is seldom justifiable. In the case of a uterine discharge for which no pelvic origin is apparent, general tonic and hygienic treatment should be given a fair trial before resorting to curettage or to any intrauterine manipulations.

Delirium in Tetanus.—C. W. Burr remarks on the rarity of mental symptoms in tetanus; the toxin does not usually appear to disturb the intellectual functions and the emotional control, considering that the patient's usual knowledge of the seriousness of the disorder, is commonly better than might be expected. When mental symptoms do occur, therefore, the question arises whether they are accidental complications occurring simultaneously with the tetanus and in no way caused by it; or due to the medicines, or to the direct result of the exhaustion produced by the disease or of a secondary infection set up by the primary action of the tetanus toxin. In a large experience with tetanus, he has himself seen delirium in only three cases which he reports. In one of these, Burr can find no cause save exhaustion and the influence of fever in a susceptible person. In some persons, slight fever is a distinct cerebral stimulant and a high temperature may cause wild delirium. In another of the three cases, he thinks that the delirium was entirely due to intoxication by the heroic doses of bromides and chloral employed and the third was in a person naturally unstable mentally, emotionally weak, lacking in self-control and a victim of alcohol. Any other severe and sudden stress would probably have been equally likely to disturb the mental equilibrium.

A Typhoid Epidemic from Milk.—C. N. Haskell gives an account of an epidemic of typhoid fever, occurring in Bridgeport, Conn., in August and September, 1907. In fifteen cases, thirteen positive and two doubtful, milk was consumed which was sold by one dairyman, who obtained his supply from nine different sources. Each case was carefully investigated as to history of illness, methods, samples of blood and well water, etc., but with negative result except in one case. On one farm supplying milk to this dealer there evidently had been at least one case of typhoid, and without much doubt several others unrecognized, as five persons who were or had been members of the family during the season gave a positive Widal reaction, and three of these had handled the milk. Still closer investigation traced the infection, in all probability, to a boy boarding at the farm during July and August who had probably had a mild attack of typhoid, mistaken for malaria, a year or two before. The epidemic ceased after the stoppage of milk from this source.

Operation on the Brain Without Anesthesia.—H. M. Thomas and Harvey Cushing give an account of a case of subcortical brain cyst, under the postcentral ascending convolution near its top, which was removed after a series of operations necessitated by the patient's condition, his intolerance of anesthetics and the difficulties of operation due to the high location of the lesion. The case is of interest surgically on several accounts; the situation of the lesion and consequent difficulties of operation; the occurrence of a post-operative extradural clot; the absence of cortical adhesions on the second opening of the dura; the occurrence of Jacksonian epilepsy with a subcortical tumor;; the possible origin of the cyst from a degenerated glioma, but the most important and suggestive fact is that the last operation in which the dura and postcentral convolution were incised, the cyst discovered and shelled out, was performed without anesthesia, the patient being per-

fectly conscious, but feeling no sensation whatever from the cutting and manipulation even when the dura was being incised. An experimental tension on the dura caused slight momentary discomfort, but this and the putting in the scalp sutures at the end of the operation, with the possible exception of the chance sponging of the edges of the incision, was the only part of the operation that caused any sensation whatever. The entire procedure lasted about three hours, the patient being interested, asking frequent questions and being engaged in conversation most of the time. Cushing has since had another similar experience of a second-stage extirpation operation without anesthesia in a young child. He says that, while further investigations in this direction are needed, this experience suggests that we may have to modify, in some respects, our notions as to the cause of intracranial pain, just as we have had to change our ideas of what causes visceral pain in the abdominal cavity. The dura, like the peritoneum may be sensitive only to tension or pressure and not to surgical incision. The article is illustrated.

Anthracite Coal Ash as a Surgical Dressing.—W. Irving Clark, Jr., recommends the use of anthracite coal ash as a surgical dressing in cases in which frequent changes of dressings are necessary, and in which the question of expense is of importance. It is readily obtainable, is neutral in reaction, and on careful analysis is found to contain no irritating substances. When freshly taken from the furnace it is aseptic, though not antiseptic. The only preparation required is sifting through a flour sieve; it can then be put on a piece of well-washed cloth, which is folded over it, making a poultice, which can be rapidly prepared and will be found soft, compact, and absorbent. It is readily molded to any part, and, while not so quickly absorbent as gauze, it draws the pus better up into the pad instead of spreading it over the skin as gauze frequently does. His conclusions are given as follows: 1. In cases in which gauze can not be obtained or the expense is too great, ash pads form a good substitute. 2. In freely discharging sinuses and suppurating wounds the discharge will be well taken care of. 3. When the discharge is thick and gummy, or when weight and bulk of dressing is contraindicated, they should not be used. 4. They are particularly applicable to discharging wounds of the axilla, popliteal space and palm of the hand, because they fit snugly and tend to splint the part. They are also well suited to varicose ulcers and discharging sinuses of the abdomen.

Non-fatal Serum Reaction.—A. P. Ohlmacher reports two cases of severe reaction to therapeutic serum injections. In both cases the contingency of hypersusceptibility had been considered and attempted to be met by administering several "immunizing" injections during the first eight or ten days of what is shown by animal experimentation to be the sensitizing interval. In both cases, the more common "accelerated reaction" of the serum disease, as defined by von Pirquet and Schick, *i. e.* urticaria, joint pains, and fever, failed to appear. It seemed as if these more usual manifestations accumulated and took the form of one grand explosion. The first case was that of a woman, expecting confinement in a short time, who was suffering from a chronic polyarticular rheumatism. For this she was given injections of antistreptococcic serum, 10 c.c. daily, for three days, and then at longer intervals. There were no evidences of serum reaction until the seventh injection on the fifteenth day of the treatment, when there was a sudden attack of very pronounced edema, cyanosis, feeble rapid pulse, severe apnea, and unconsciousness. After what seemed several minutes, but, of course was less, gasping inspiration occurred, followed by a rapid recession of the edema and cyanosis, with spasmodic breathing, moaning, and gradual return of consciousness. As soon as the patient was able to talk she complained of chilliness, and severe rigors occurred, with vomiting, which together lasted about fifteen minutes. Following the chills the cutaneous surface took on a bright red hue and fever gradually developed, reaching a maximum of 103° F. in about three hours. All had subsided by the next morning; the woman expressed herself as feeling perfectly well, and for a week or two the rheumatic joints were much more comfortable. Ohlmacher says the good results following the injection of horse serum in chronic rheumatism are due to the periodic hyperemia in the affected joints by the "accelerated serum reaction." Some fears were felt for the child *in utero*, but all went well. In the second case, that of an adult man, the cumulative reaction was not so severe, principally differing in that the apnea was less prolonged and consciousness not entirely lost. There was also a longer interval (three minutes between the injection and the appearance of the symptoms, but in other respects the cases were similar, even to the relief of the rheumatic symptoms.

The Lancet, March 7, 1908.

Warning Against the Indiscriminate Use of the Ophthalmo (Calmette) Reaction in the Diagnosis of Tubercle.—A. M. Ramsay refers to the case of a girl of 12 years admitted to the Glasgow Royal Infirmary suffering from superficial vascular ulceration of the right cornea. There was a history of a similar attack in the left eye two years before, and though careful examination revealed no sign of tubercle in the lungs or the abdomen both cervical and submaxillary glands were much enlarged. On the 10th one drop of a 1 per cent. solution of tuberculin was instilled into the left eye which was at that time perfectly free from inflammation, although there was a faint nebula on the cornea, the result of the previous attack of ulceration. Within 24 hours there was violent mucopurulent reaction, the discharge being very abundant and accompanied by marked swelling of the lids and thickening of the palpebral conjunctiva. The inflammation could not be influenced by treatment, and progressed till the cornea quickly became vascular and abraded over the central area. On the 20th 0.25 cubic centimeter of a 1 in 1000 solution of Koch's old tuberculin was injected subcutaneously. This was followed by a rise in temperature and resulted in great improvement in the condition of the right eye though the left remained unchanged. Subsequently the old tuberculin was again injected twice, the first time to the amount of 0.25 cubic centimeter and the second time to the amount of 0.5 cubic centimeter, and by the end of November the right eye was almost quite recovered, while in the left the discharge had begun to lessen. After that date the improvement in the latter was steady but there remains as a result of the Calmette instillation a considerable opacity of the center of the cornea, and in consequence the vision is seriously impaired.

Egg Poisoning.—A. T. Schofield states that while egg poisoning is not rare he has been unable to find any record of cure. He reports the case of a boy of 13 years whose parents stated that he could not eat eggs in any form without poisonous symptoms. In the attacks there was first of all free secretion of saliva, the lips burned, the boy felt sick, itched, and was soon covered with an urticarial rash. He swelled all over, with puffy eyelids and lips, tight red swollen skin, and could hardly breathe from a sort of asthmatic condition. Raw egg would blister his skin. The author endeavored to remove this susceptibility and commenced his treatment by the constant administration of egg with a little calcium lactate added to stop the transudation. Pills were made containing two grains of the calcium salt and one ten-thousandth part of a raw egg. No eggs were permitted in his food and he was not allowed to know there was any egg in the pills. The egg proportion was gradually increased until in the course of six months he was able to consume an egg daily in his food, the pills being discontinued. The author says that some may think a great deal of trouble was taken to cure this idiosyncrasy, but when we remember that it was not connected with some rare food such as pineapple, which could easily be avoided, but with an article that enters into nearly all a schoolboy eats, and that his life had been more than once in danger from such food, it will be seen that the trouble taken was amply justified.

Seven Years' Experience of Finsen Treatment.—J. H. Sequeira gives a statistical report of his experience with this agent in 599 cases of various maladies. Of this number 429 were cured, 107 improved, 23 failed, 25 preferred other treatment, while 15 died. The list of cases includes 68 of lupus erythematosus, 14 of rodent ulcer, 5 of cutaneous nævi (all improved), a few of pigmented mole (all failures), one of leucodermia (failure), a few of keloid (all benefited), and some of telangiectasis in *x*-ray scars (all benefited). The author goes quite extensively into the physics and apparatus of the agent employed. In 23 cases the treatment had to be abandoned on account of the great extent of the disease, the rapid spread of the malady in spite of all efforts and extensive involvement of mucous membranes. At times it was found that every application of the light would lead to the formation of an ulcer. The author believes that such cases always present mixed coccal and tuberculous infection. As a rule such cases respond well to the simple *x-ray*. In certain extensive cases the Finsen treatment was discontinued in favor of the *x*-rays as it was found that the former was unable to keep pace with the rapidly extending surface. Again, some limited cases of lupus of the extremities and trunk, where the character of the scar was immaterial, were treated by excision after the light treatment had been started.

British Medical Journal, March 7, 1908.

The Reduction of Displaced Internal Semilunar Cartilage.—H. W. Jacob says that the following method

is simple, absolutely painless, and if the patient has not himself already manipulated the joint or endeavored to walk is practically unattended with synovitis. The patient lies on a bed or couch, the surgeon standing on the outer side of the limb affected, with his face towards the patient's foot; the patient then raises his leg off the couch in the semiflexed condition, the surgeon grasps the patient's leg in both hands, and using his own thigh as a fulcrum, by means of a steady pulling movement draws the patient's leg outwards while the surgeon's thigh keeps the patient's femur in a fixed position; directly this movement is effected the patient must steadily extend the limb, and the displaced cartilage will probably go back with a slight click; if the first movement of extension is not successful the maneuver must be repeated without any hurry or unnecessary force, and after a few attempts the cartilage can usually be felt to slip in without pain or inconvenience. The author believes that the levering outwards of the patient's leg reduces the resistance to the backward passage of the semilunar cartilage, which then slips back into place with the aid of gravity.

Sugar Headaches.—T. M. Allison believes that many of the so-called "bilious" attacks are due to an excessive intake of sugar. The sugar standard of nature is the quantity found in milk. The excess taken in food (not alone as sugar, but also as starch, which in body metabolism becomes sugar) is converted into lactic acid, which irritates the terminations of the gastric vagus and sets up the well-known but badly-named "bilious attack," with its distressing symptoms of "megrim," of which the commonest is hemi-headache, generally referred to the left eyeball and relieved by pressure, together with vomiting, giddiness, and depression. The author says that if sugar were expensive instead of being cheap, there would be many less puzzling cases of headache for which eyestrain, hereditary, and various other factors are assigned.

A Typhoid Carrier of Twenty-nine Years' Standing.—The patient of G. Dean was a physician who had had, twenty-nine years ago, an attack of typhoid fever. Since that time he has had many attacks of what he regarded as biliary colic. They were generally associated with over-exertion, long bicycle rides and irregular meals. Jaundice occurred in some of them. Between attacks his general health was good and he was able to carry on his professional duties. It was suggested to him that he might be a typhoid carrier and the proof of this assumption was demonstrated by the customary bacteriological tests. So far as was known he had never infected anyone, and this fact points, says Dean, to the conclusion that with educated people in fairly hygienic surroundings, and where personal hygiene is carefully attended to, the risk of infecting others is not so great as might be imagined. The very definite history of the first attack of biliary colic in a young man occurring three months after typhoid fever, strongly suggests that the calculi were the result of the infective processes. Agglutination tests with the patient's own serum were made, and it was found that with the bacillus ordinarily used in the author's laboratory for the Widal test the patient's serum gave an agglutination in a concentration of 1 in 25, but failed to do so in 1 in 50, and 1 in 100. With the patient's own bacillus the serum failed to produce agglutination even in 1 in 25. That the absence of this reaction with the patient's own serum is not due to the lack of suitable receptors in the bacillus is proved by the fact that it was capable of being agglutinated by immune horse serum.

A Case of Actinomycosis (Streptothrichosis) of the Lung and Liver Successfully Treated with a Vaccine.—The case of W. H. Wynn is of importance because it adds one more to the number of infections which have been successfully treated with a specific vaccine prepared from the infecting organism. The patient was a schoolboy of fourteen years, who developed a fluctuating swelling below and to the left of the nipple in the sixth intercostal space. About eight ounces of offensive pus were evacuated and a ragged cavity could be felt with the finger running up toward the axilla and apparently in the lung itself. The main portion of the paper following the history of the case refers to the bacteriological and culture tests and the manufacture and use of the "actinomycotin" serum. There was not much difficulty in preparing the serum, as the organism was isolated and grown in pure culture. The boy had suffered all his life from bronchitis. The case emphasizes the importance of the systematic importance of the sputum, especially in cases resembling tuberculosis in which no tubercle bacilli can be found, and of the pus in all cases of empyema, especially those which show a perforative tendency.

The Diathesis; the Personal Factor in Disease.—Dyce Duckworth notes that one result of modern study is to lead us to regard men as living units with an exact bodily conformation, a uniform trophic system, and tissue metabolism, and to disregard textual peculiarities, definite proclivities, and variants of intimate metabolism. Such a view is evolved in the laboratory, but is contradicted at the bedside, for the clinician is always faced with the personal factor in each patient. We may recognize from special types of body, arthritic, scrofulous, or lymphatic, nervous, and bilious. Those who are subjects of the arthritic type plainly show their liability to rheumatic infection, which the author terms *exogenous*, and no less to the onset of gout, a malady which he regards, in the absence of exact proof to the contrary, as due to endogenous toxins, derived from perverted metabolism in the individual. He notes that some English authorities are disposed to regard the toxic element of gout as generated from intestinal microbes, but as there are people who under provoking conditions do not become rheumatic, so with reference also to gout. Many of the arthritic diatheses are resistant to tubercle. Duckworth declares his belief in the existence of a distinct scrofulous type. Scrofula for him is not tubercle. The nervous type is shown by those of an over-sensitive and delicate nervous system, with a tendency to instability, to the several neuroses, and to mental aberration. The term "bilious" is suggestive of hepatic overactivity, but the main incapacity of such subjects lies in the digestive system and in many instances is due rather to hepatic inadequacy. We often meet, as may be expected, with blends of this constitution with others, as in the case of neurobilious or bilious arthritic subjects. One striking peculiarity of this tendency is the toleration for, and beneficial influence of, mercury in many of the ailments suffered by persons of bilious habit. No other drug can replace mercury in such cases. This is in marked contrast to its effects on persons of the scrofulous constitution who bear it badly.

Berliner klinische Wochenschrift, March 2, 1908.

Myelogenous Leukemia.—Lehndorff and Zak discuss the nature and pathogenesis of leukemia in the light of a case observed by them in which a clinically and hematologically well marked myelogenous leukemia occurred in a person of advanced age, the marrow of whose long bones had been converted into a fibrous tissue having practically no specific marrow cells, whereas the spleen showed a high grade of myelogenous change. This state of affairs is difficult to explain on the basis of the ordinarily accepted theory of disease, which is usually accepted as a primary overgrowth of the bone marrow. The authors point out, however, that it has now been definitely shown that under pathological conditions of the most varied nature, and also in leukemia, myelogenous tissue appears in numerous organs such as the spleen, liver, lymph glands, etc., either through hyperplasia of preexisting areas or as the result of metaplasia of the lymphoid cells. It is, therefore, not necessary to assume that in myelogenous leukemia there is a primary disease of the bone narrow, but the affection may be regarded as a disease of the entire hemopoietic lymphatic system. Ordinarily the bone marrow responds most actively to the stimuli of the morbid process, but the changes in this tissue are not themselves essential to the picture, and such instances as that under consideration are simply examples in which the bone marrow has been less extensively involved, without, however, altering the true character of the disease.

Münchener medizinische Wochenschrift, March 3, 1908.

The Hemolytic Action of Ankylostoma Duodenale.—Preti tested the hemolytic properties of this parasite and obtained results somewhat similar to those reported by Talqvist in regard to the *Bothriocephalus latus*. The worms were washed out of the feces and then triturated in salt solution, the resulting cloudy fluid being used for the experiments. It was found that the worms contained a substance which was hemolytic for the corpuscles of many animals, such as man, the dog, rabbit, ox, and guinea pig, but that this was insoluble in salt solution and was retained by the filter on filtering the suspension. It was, however, soluble in alcohol and in ether. The substance is thermostable and its activity is not impaired by three hours of heating in a boiling water bath. At a temperature of 0° it is still active though but slowly. The addition of lecithin increases the potency of the hemolysin, but without the formation of a true lecithid, and cholesterin does not neutralize this. Trypsin digestion liberates the hemolysin and renders it water soluble. The alcoholic ex-

tract of the worms possesses neither tryptic nor antitryptic properties. In order to hemolyze one c.c. of 5 per cent. corpuscle suspension 2.5 mg. of moist worm body are required.

Saponin Inhalations in Diseases of the Upper Air Passages.—Zickgraf says that W. Freudenthal was the first to point out the significance and frequency of simple dry catarrhal conditions of the upper air passages. While it has been well known that the last stages of such conditions, the true ozena, predispose to pulmonary tuberculosis, it is also true that from the first the forerunners of these trophic changes are of importance from this standpoint. For the treatment of such atrophic mucous membranes he recommends quillaja or soap bark. At first he employed this in the form of irrigations, and later of inhalations of a one per cent. decoction, but he now finds that the most satisfactory method of application is by inhalation of saponin solution. In milder cases a one per cent. solution is used and in severer ones a two per cent. solution. The inhalation is effected by means of a suitable nebulizing apparatus and is kept up for three to five minutes. The effect of the vapor is to cause a very active secretion of mucus and a thorough cleansing of the nasal passages, the patients frequently expelling crusts that are casts of almost the entire cavity. The atrophic mucous membrane becomes filled with blood and grows moist, while the fetor is promptly relieved so that the patient is no longer an objectionable member of society. Mild cases can be cured in this way, and the severe ones greatly relieved. In some instances it appears as if under the treatment there is a slight return of the long-lost sense of smell.

Thermal Medication in Gynecology, Obstetrics, and Urology by the Bock-Samovar and Its Accessories.—Nicholas de Plantier describes the construction and use of the Bock-Samovar, an arrangement by which the hot water for a vaginal douche can be kept hot for an hour or more while it is slowly allowed to flow out. The heating is maintained by means of a charcoal block placed in a slide at the bottom of the douche pan. This is lighted after the hot water has been introduced into the can and is kept alight during the douche. The patient is able to lie at ease and is not obliged to rise to refill the bag with hot water. The value of hot water applications is due to the keeping of the water at a uniform temperature of about 45° to 50° for a considerable length of time. These requirements are fulfilled by the Bock-Samovar. The instrument is furnished with cannula for the vagina, rectum, and uterus. The vaginal cannula has a double current, and is of porcelain, which is easily sterilized and is a bad conductor of heat. A thermometer serves to regulate the temperature of the water. The author has synthetized the salts of various springs so that they can be used with this apparatus. It is recommended for treatment of puerperal infection and metrorrhagia postpartum, the cannula being arranged in such a way that it is impossible for any fluid to remain in the uterus. It is made of different sizes, smaller for abortions under six months, and larger for labor at term.—*Annales des Maladies des Organes Genito-Urinaires*, November 1, 1907.

The Reaction of Bordet and Gengou in Its Relation to the Streptococcus in Scarlatina.— C. Foix and E. Mallein have applied the reaction of Bordet and Gengou to scarlatina. It has been shown that it is possible to prevent the hemolysis of a mixture of complement, sensibilizer, and red blood corpuscles by fixation of the complement. This fixation is obtained by the use of a counter mixture obtained from bacteria and antibodies. The authors made a mixture of sensibilizer from the serum of the rabbit injected with human blood. The complement was furnished by serum of a guinea-pig. The streptococcus was furnished by successive bouillon cultures of scarlatinous exudation of the throat. They examined twelve cases of scarlatina, from the fourth to the thirty-eighth day of the disease. The reaction became more delicate as the age of the disease increased. Ten of the twelve patients gave positive results, the hemolysis being markedly delayed. The conclusions given are these: the serum of scarlatina contains antibodies directed against the streptococcus. This occurs as early as the fourth day and as late as the thirty-eighth day. It remains to prove whether this reaction occurs with all sorts of streptococci or only with scarlatinous streptococci. This reaction may be made use of in serodiagonsis.—*La Presse Medicale*, November 30, 1907.
